The most important work of the machine designer is not merely to produce a mechanism that will function mechanically, but one that will meet this requirement and that also can be sold at a price which will insure for it a market. A widely known machine tool designer has said that anybody can design a machine to do almost anything, but that it takes real brains to design a machine that will do what is wanted at a reasonable cost.

This is one reason that accurate and complete information on shop methods and manufacturing procedure is so important. The successful machine designer must not only know how to design a machine or apparatus that will function according to mechanical laws, but he must also understand how the machine is to be built and how the parts are to be machined and assembled, so that every part incorporated in the machine will be so designed and arranged that it can be produced at the minimum cost. That is real machine designing, and in order to impart to designers this knowledge, publishers have brought out better literature on modern shop methods. The designer's needs have not been neglected thereby; they have been taken better care of.

Spring Meeting of Mechanical Engineers

AT the spring meeting of the American Society of Mechanical Engineers, held at Atlanta, Ga., May 8 to 11, mechanical engineering problems that are especially pressing for solution in the South were dealt with. A great deal of attention was given to the design, construction, and maintenance of textile machinery. A session of considerable interest in the machine-building field, relating to oxy-acetylene, electric, and forge welding methods, proved of great value to the engineers present. The technical program of the meeting was spread over three days and included two general sessions, two textile machinery sessions, and one session each on materials handling, fuels, power, management, and welding.

Investigations Relating to Oxy-Acetylene, Electric and Forge Welding

In a paper entitled "The Strength of Electrically Welded Pressure Containers," R. J. Roark of Madison, Wis., described pressure tests made on electrically welded, gas-welded, and riveted pressure containers, and tension and shear tests made on specimens cut from such containers and on specially prepared specimens of welded metal. The tests were made for the Vilter Mfg. Co., of Milwaukee, Wis., and had for their purpose the demonstrating of the strength and uniformity of construction in which the electrical weld is employed.

The results of the tests indicate that in containers of the type studied, electrically welded head joints are sufficiently strong to develop the full strength of the shell and heads; that it is practicable to make electrically welded joints which are uniform in respect to tensile strength, shearing strength, and structure of fused metal; that for the particular combination of metals tested, the tensile strength of such welded joints is about 28,500 pounds per square inch and the shearing strength about 25,500 pounds per square inch; that for the combination tested, the metal in the weld is less strong and less ductile than either the base metal or the filling metal before fusion; that the electrically welded joints tested were stronger in shear but weaker in eccentric tension than the riveted joints tested.

An extensive paper dealing with the principles of construction of unfired pressure vessels was prepared by S. W. Miller, of the Rochester Welding Works. In this paper the author discussed, in general terms, forge and fusion welding and riveting, and commented on the factors affecting welding efficiency. The composition of the best base weld metal and welding wire was touched on, and proper welding conditions were mentioned. The weakness of the single V-weld was pointed out, and the use of lower-tensile-strength material advocated. The question of relieving welding strains by annealing was also treated, these and the foregoing observations being all based on the practical experience of the author.

Professor E. A. Fessenden and Professor L. J. Bradford, both of State College, Pa., had prepared a paper giving the results of tests made on welded cylinders, in which four types of construction were referred to: (1) Flange-steel shell, acetylene-welded longitudinal seam, concave heads forge-welded to shell; (2) seamless-pipe shell, convex heads acetylene-welded to shell; (3) seamless-pipe shell, concave heads forge-welded to shell; and (4) flange-steel shell, acetylene-welded longitudinal seam, convex heads acetylene-welded to shell. This paper described the method of conducting the tests, presented the data obtained, and discussed the results. The authors concluded that vessels having forge-welded heads are the least reliable and that burnt steel is often present in the weld. They also stated that the principal defects in acetylene welds are the coarse granular structure and occasional porous spots and pin-holes that develop with high pressures, and poor adhesion of the welding material. Remedies for these defects were proposed.

Another paper of interest in connection with welding practice was that presented by Frank N. Speller, of the National Tube Co., Pittsburg, Pa., in which the principal factors—the method of manufacture, chemical composition, fluxing quality, susceptibility to heat and welding temperature—affecting the welding quality of steel were discussed and the average results of eighty tests made on forge welds of hammer-welded pipe, as compared with the original material were given. Tests have demonstrated that steel with not over 0.15 per cent carbon and a minimum tensile strength of 47,000 pounds per square inch, and with not over 0.20 per cent carbon and a minimum tensile strength of 52,000 pounds per square inch, is satisfactory for forge-welding of pipe lines, penstocks, tank-car work, and similar construction.

Care and Maintenance of Textile Machinery

The maintenance of textile machinery was dealt with in a paper by Edwin H. Marble, president of the Curtis & Marble Machine Co., Worcester, Mass., particular attention being called to the value of ball bearings in textile machinery, and the importance of proper lubrication. Reference was also made to a number of the common abuses of textile machinery and means suggested for preventing neglect in the care of this type of machines.

A paper on weaving machinery, by L. B. Jenckes of the Compton & Knowles Loom Works, Worcester, Mass., described in a general way the development of the weaving art, and dealt briefly with the most interesting developments in modern looms and the functions of parts of these machines.

The paper "Modern Shop Practice in the Building of Revolving Flat Cards," by F. E. Banfield, Jr., Newton Upper Falls, Mass., gave details of special machines developed for this work and showed how much the production cost per unit has been lowered by efficient shop arrangement, careful machine design, and standardization.

Material-handling Equipment

The material-handling equipment used in the iron and steel industry was dealt with in a paper read by F. L. Leach, of Perin & Marshall, New York City. This paper described the handling machinery and apparatus used in the manufacture of steel. From the time that the ore leaves the mines until the steel goes through the last process at the mill it is moved about by different types of heavy machinery designed especially for the purpose. The author expressed the hope that through his description, attention will be given to weak points in present-day practice and means of improvement be suggested.

Power and Fuel Session

The papers relating to power and fuel dealt with "Power Development in the Southeast"; "Economics of Water-Power Development"; "Hydro-electric Power-plant Design"; "The Accuracy of Boiler Tests"; "Boiler-room Performance and Practice of Colfax Station, Duquesne Light Co."; "The Control of Boiler Operation"; "Efficiency Tests of a 60,000-kilowatt Cross-compound Triple-cylinder Steam Turbine"; "Using Exhaust Energy in Reciprocating Engines"; and "Reduction of Fuel Waste in the Steel Industry."

Copies of any of the papers mentioned may be obtained upon application to the American Society of Mechanical Engineers, 29 W. 39th St., New York City.

The Gleason Works System of Bevel Gears*

By F. E. McMULLEN and T. M. DURKAN of the Gleason Works, Rochester, N. Y.

For a long time a need has been felt for a definite system of designing bevel gear teeth, which would give the most desirable tooth form for use under average conditions. It has been common practice in the past to use spur gear formulas, such as those of Brown & Sharpe, in figuring bevel gears. These formulas were worked out for an interchangeable spur gear system, which necessarily required some compromise, so that when they are applied to bevel gears, where interchangeability is not a factor, the possibilities of the involute curve are not fully utilized. The Gleason 0.3 and 0.7 long and short addendum tooth was brought out to improve this condition, and various other alterations of the standard spur gear design have been used, but for the most part these can be applied to certain combinations only, and therefore are not universal. Recent applications of bevel gearing covering a wide range of ratios have made it imperative that a system embracing all ratios and any number of teeth in common use, be worked out.

An investigation has been conducted by the Gleason Works with the idea of developing a practical system of designing the quietest form of tooth consistent with strength and wear considerations, and the results of this research have been incorporated in simple tabular form. This system applies to any pair of generated spiral or straight-tooth bevel gears operating at right angles where the pinion is the driver and has ten or more teeth. Bevel gears cut on former-type planers are the subject of a special study, as the system cannot be applied to such gears without modification.

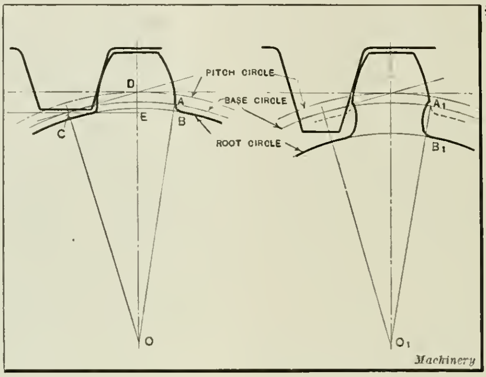

Fig. 1. Involute Tooth in Mesh with Rack

Fig. 2. Longer Rack Tooth and Resulting Under-cut

Factors Governing Selection of Pressure Angle

The principal qualities considered in arriving at this system, arranged in the order of their importance, are quietness, strength and durability. In regard to quietness, experience shows that bevel gears cut with a lower pressure angle will operate more quietly than those with a higher one, other conditions being equal. There are several reasons for this: When the lower pressure angle is used, a greater arc of action is obtained, any eccentricity has less effect, and the radial component of the tooth load is minimized. Thrust forces also make it desirable to avoid the higher angle, not only because of the introduction of an axial or cone thrust not present in spur gears, but also because the majority of bevel gears are overhung from their supports, so the total load should be kept as low as possible. For these reasons the basis of the system is the use of the lowest pressure angle that can be employed without sacrificing strength by introducing excessive under-cut.

Under-cut in Connection with Bevel Gears

It might be well to describe what is meant by under-cut. In Fig. 1 is shown an involute tooth in mesh with a rack. The tooth profile consists of two parts, namely, the involute curve which has its origin at *A* and continues to the top of the tooth, and the fillet *AB* lying between the base and root circles. If the rack, which represents the generating tool, does not project below point *C*, beyond which involute action cannot take place, the fillet *AB* will always lie outside of a radial line *OA* drawn from the origin of the involute. When the rack tooth is made longer so that it extends below point *C*, the condition is as shown in exaggerated form in Fig. 2. In this diagram the fillet A_1 B_1 is seen to come inside of a radial line O_1 A_1 and also to cut away part of the involute curve slightly.

An examination of Fig. 1 shows that the value for dimension *DE*, which is the distance from *C* to the pitch line, is equal to the back cone radius *DO* $\times$ $\sin^2$ pressure angle so that a generated bevel gear tooth may be said to be under-cut when the dedendum is greater than the back cone radius $\times$ $\sin^2$ pressure angle. However, it can be shown mathematically that it is possible to exceed this value consider-

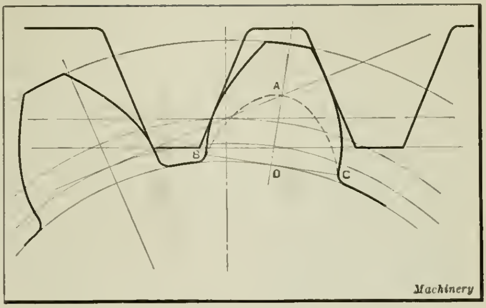

Fig. 6. Spiral Bevel Gear of 10—47-tooth Ratio and 20-degree Pressure Angle

ably before there is any appreciable under-cut; in fact, for the ordinary automobile rear axle pinion having anywhere from ten to thirteen teeth, the dedendum is nearly always more than this critical value, sometimes being as much as 100 per cent greater. The point at which to limit under-cut in the present system has been determined by a study of successful automobile practice, because that application represents a condition where both silence and strength are paramount.

The 10–47-tooth 14½-degree spiral bevel ratio shown in Fig. 3 has a pinion dedendum 60 per cent greater than the back cone radius × sin² pressure angle, and although the under-cut is about as great as for any job in the spiral bevel system, it cannot be called excessive. Likewise, the 14–16-tooth 14½-degree straight bevel gears shown in Fig. 4 represent as extreme a case of under-cut as will be encountered in the straight-tooth system; yet they have a tooth profile which is not weakened to any great extent. The same ratio with a 17½ degree pressure angle is shown in Fig. 5, but the strength of the gears is increased less than 5 per cent, although it has the appearance of being more than this.

Pressure Angle and Strength

The selection of a low pressure angle in preference to a higher one does not result in a considerably weaker tooth, as is ordinarily supposed, because the stronger section of the higher pressure angle tooth is offset by the greater arc of action with the lower angle. Reference to Figs. 3 and 6 will make this clear. Fig. 3 shows a 10–47-tooth ratio with a 14½-degree pressure angle, and in Fig. 6 the same ratio is laid out with a 20-degree pressure angle. In each case the pinion tooth at the left is just on the point of engaging so that the tooth at the right is carrying the full load. This is the worst condition of loading on each tooth as any further movement to the right brings another tooth into contact, with consequent distribution of the load over two teeth, while movement to the left lowers the line of application of the force toward the base of the tooth.

In this position the comparative strength of the teeth can be found by passing a parabola through the intersection point A (See Figs. 3 and 6) of the line of action and the center line of the tooth, and tangent to the tooth profile. The value of $(BC)^2 \div AD$, which is a measure of the strength, can then be obtained. For the 10–47-tooth ratios shown in Figs. 3 and 6, the 20-degree gear is about 14 per cent stronger than the 14½-degree gear, but the pinions are of equal strength. The 20-degree gear, however, is much more difficult to caseharden on accouut of the narrow width of the top land. A pair of 15-tooth 14½-degree and another pair of 15-tooth 20-degree miter gears are shown in Figs. 7 and 8; here the 20-degree gear is less than 10 per cent stronger than the 14½-degree gear.

This method of calculating the strength is similar to that used in deriving the Lewis formula, except as regards the point of application of the load. The Lewis formula is based on the assumption that the load is applied at the end of the tooth, but in modern generated gearing this is a condition that practically never occurs. Professor Marx, in his experiments at Leland Stanford University, found that the force was not at the end of the tooth when failure took place, and also proved that the strength was increased as the arc of action became greater. From a consideration of these conditions, it is evident that the choice of a 14½-degree instead of a 20-degree pressure angle is not made at any extreme sacrifice of strength, but that for a large number of designs there is very little difference between the two.

Wear as Related to Sliding Action and Unit Pressure

The question of durability, viewed from a theoretical standpoint, would seem to resolve itself into a problem of obtaining a minimum of sliding and a maximum of rolling motion, as it is natural to assume that the wear would vary directly with the sliding action. But it is well known that the greatest wear often takes place near the pitch point where there is no sliding action. This is because the big factor causing wear is unit pressure and not sliding action. When the

point of contact is near the pitch point, all the load is borne by one tooth, while it is distributed over two teeth near the beginning or end of the action with a consequent reduction of unit pressure.

In Figs. 7 and 8 the part of the pinion profile that will wear most rapidly is *FG*, because it has to carry the whole load; *EF* and *GH* will not wear as fast, even though the sliding action is higher, on account of the lower unit pressure. For this reason no attempt has been made in this system to maintain any predetermined percentage of rolling action, but rather to balance, between approach and recess, the amount of rolling already fixed by the requirements of quietness and strength. Wherever possible, the action during approach has been favored in order to compensate for the change in direction of the friction component which tends to increase the obliquity of the line of action during approach and decrease it during recess. Account has also been taken of the high velocity of sliding action which occurs

Machinery

at the top of long addendum pinion teeth and which, in extreme cases, has led to abrasion. Safe values for this sliding action were obtained from jobs in service and the design regulated so that these were not exceeded.

How the System was Established

In establishing the various factors that go to make up the system, the aim was to arrange them in as simple and practicable a form as possible without sacrificing any of the three principal qualities of quietness, strength, and durability. In a non-interchangeable system like the one here presented, any of the factors can be made to vary for each ratio and number of teeth, but simplicity and the interests of standardization are opposed to expressing these factors as variable quantities when the probable accuracy of the assumptions made in determining them does not warrant it.

An example of this is the pressure angle. In a purely theoretical system it might have any value, while the same practical results are obtained in this system, which includes all ratios having ten or more teeth in the pinion, with the use of three angles (14½, 17½, and 20 degrees) for straight-tooth bevel gears and one angle (14½ degrees) in all except a few unusual cases, for spiral bevel gears. The pressure angle to be used for any given pair of gears is specified in Tables 1 and 3, and has been selected as the lowest angle which avoids excessive under-cut.

The introduction of the pressure angle of 17½ degrees, which is not universally used, is considered necessary in order to carry out the stated purpose of developing a practical system which will give the quietest form of tooth consistent with strength and wear. It has been found by experience that there is a decided increase in noise when the pressure angle is changed from 14½ to 20 degrees, so that in order not to compromise the system when the under-cut becomes too great with 14½ degrees, an intermediate pressure angle is used. The angle of 17½ degrees has been selected because it has already been used to quite an extent by different gear manufacturers. Although at least one pressure angle between 14½ and 20 degrees is required, more are unnecessary because any new angle would not be more than 1½ degrees different from the three selected, and this change is too small to have any practical effect.

Working Depth and Clearance

The working depth of tooth, which has been fixed as 2 inches ÷ diametral pitch for straight-tooth bevel gears and as 1.7 inches ÷ diametral pitch for spiral bevel gears, is the same as has been successfully used for a number of years. For the average spiral angle of about 30 degrees, the normal pitch is approximately 85 per cent of the linear pitch, so the normal section of a spiral tooth will be proportioned about the same as a straight tooth. Originally the working depth for both straight and spiral bevel gears was made equal to 2 inches ÷ diametral pitch, but some years ago the depth for spiral bevel gears was decreased to 85 per cent of this amount, because the top of the tooth on the normal was too thin and gave rise to hardening troubles. Stubbing the tooth more than 85 per cent decreased the arc of action and gave a noisier gear. It would be desirable from the standpoint of standardization to use the same working depth for straight-tooth bevel gears as for spiral bevel gears, but after considerable experimenting along this line, it was found that straight bevel gears having an 85 per cent stub tooth were noticeably noisier in operation than similar gears with the full depth tooth. For this reason the standard of 2 inches ÷ diametral pitch has been retained for straight-tooth bevel gears.

The bottom clearance which is specified in the system is 0.188 inch ÷ diametral pitch (0.06 × circular pitch) and is the minimum amount which experience shows is necessary for the average job to insure against bottoming of the teeth. In the past 0.05 × circular pitch has been used and found to be insufficient, while 0.07 × circular pitch which has also been tried out, is more than is required.

Addendum and Circular Thickness

The method followed in proportioning the addendum and dedendum was to adjust them until the amount of sliding during approach was about the same or slightly less than the sliding action during recess. This also had the effect of making the arc of recess greater than the arc of approach, which is very desirable, since recess action is quieter than approach. To obtain these conditions, it was necessary to decrease the gear addendum and increase the pinion addendum as the ratios of the numbers of teeth in the gear and pinion became greater. These values of addendum for gear and pinion were originally worked out for each ratio and number of teeth, and from an examination of them it was found possible to make an arrangement in a simple tabular form according to ratios (see Tables 2 and 4) without any sacrifice of practical qualities.

Circular thickness was found entirely by making enlarged lay-outs in which the teeth were balanced up partly on a width of top land and partly on a strength basis. The formulas given in Tables 1 and 3 were worked out so that they would give the same results that were obtained from the lay-outs.

This system is not new or untried, but in the case of spiral bevel gears, at least, is represented in practice by a large number of very satisfactory jobs. It also checks up closely with successful straight-tooth bevel gear practice, although the long and short addendum tooth has not been used as universally for straight-tooth bevel gears as for spiral bevel gears. The system, as presented, represents in a simple and usable form an intensive study of the question of bevel gear tooth design, treated from both a practical and a theoretical standpoint.

It might not be out of place to express the opinion that a standard non-interchangeable system, possibly along similar lines to the one presented, is needed for spur gears. In fact such a system should be of as great importance as a standard interchangeable system, since a large proportion of spur gears, like bevel gears, are intended to operate in pairs only. The concessions made to allow interchangeability are so great that the case of the non-interchangeable gear should be granted as much consideration in the way of a standard system as is given to the interchangeable gear.

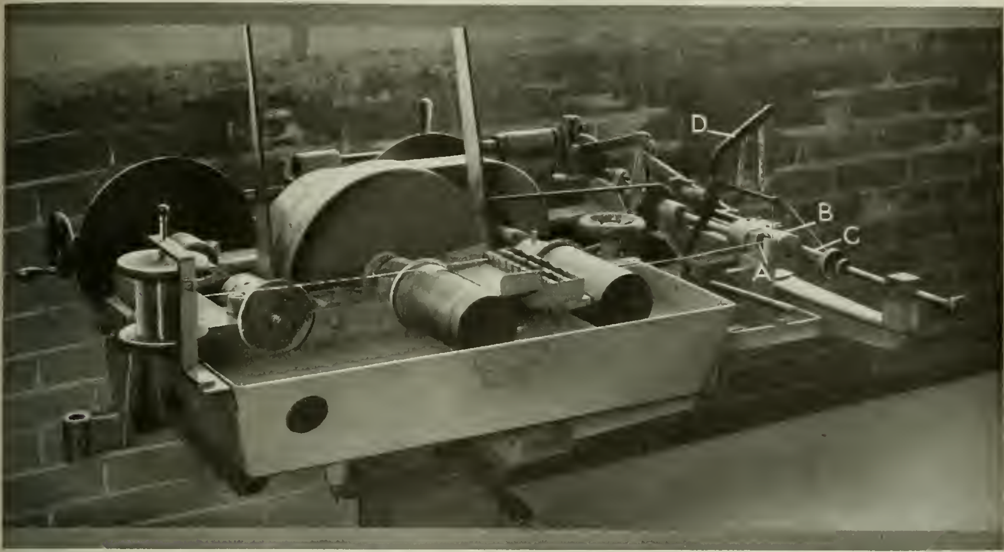
NEW SAFETY CODE FOR ABRASIVE WHEELS

A new safety code for the use, care, and protection of abrasive wheels has recently been approved by the American Engineering Standards Committee. This code has been in the process of preparation for about two years. It was prepared under the rules of procedure of the American Engineering Standards Committee, and has as its sponsors the International Association of Industrial Accident Boards and Commissions and the Grinding Wheel Manufacturers Association of the United States and Canada. These sponsors appointed a sectional committee to draft the code, consisting of twenty-eight members representing various branches of both federal and state governments, several national manufacturing associations, a number of individual employers, associations of employes using grinding wheels, several technical societies, and insurance associations.

The code gives rules and specifications necessary to insure safety in the use of abrasive wheels operating at speeds in excess of 2000 surface feet per minute. It deals with types of protection devices, storage and inspection of wheels, general machine requirements, protection hoods, work-rests, protection of wheels, flanges, mountings, speeds, operating rules, and general data. Copies may be obtained from any grinding wheel manufacturer or from the American Engineering Standards Committee, 29 W. 39th St., New York City.



Drawing Chromel Wire

Methods of Drawing Special Alloy Wire, Uses and Physical Properties of the Alloy, and Manufacture of the Dies

By E. F. LAKE

CHROMEL is the trade name for a high-grade alloy containing, in its best grade, 80 per cent nickel and 20 per cent chromium. Another grade contains 85 per cent nickel and 15 per cent chromium, while still a third grade contains approximately 61 per cent nickel, 25 per cent iron, 3 per cent manganese, and 11 per cent chromium. All other elements are classed as impurities and are held down to a minimum. Chromel alloys have an electrical resistance from fifty to sixty-five times greater than that of copper, depending on the grade of the alloy, and they also have a very high resistance to heat. The best grade is practically immune to oxidation and corrosion at temperatures up to about 2200 degrees F. The third grade, however, which contains iron, begins to oxidize at about 1500 degrees F., and this oxidation increases with the rise in temperature. Chromel is made by the Hoskins Mfg. Co., Detroit Mich.

The behavior of this alloy under high temperatures makes it suitable for use as a heating element in all kinds of electrically heated devices, from electric toasters to furnaces used for heating steel preparatory to hardening or forging. Iron-free chromel may be found in use in the thermocouples of nearly all pyrometers that work at a temperature up to 2200 degrees F. This alloy is said to be mainly responsible for the rapid growth of the electric heating industry in which it is used for heating apparatus that operates at temperatures between 1500 and 2200 degrees F. The third grade of the alloy, in which iron is an ingredient is used extensively in the construction of flat-irons, ovens, and heating devices that operate below a temperature that does not exceed the oxidizing point of the alloy. Although the alloy has many other important applications, those mentioned are the most common uses for wire that is drawn by the methods described in this article.

In the manufacture of wire, chromel is first melted and mixed in the induction-type electric furnace until all impurities are removed. It is next cast into ingots 4 inches square and 24 inches long. These ingots are reheated to about 2200 degrees F., after which they are rolled into bars 2½ inches square in four passes through the rolls. The end of these bars is then cropped off to remove the pipe, and the bars are again heated and rolled into 1¼-inch squares, in six passes. Each of these bars is next cut into two lengths, and the imperfect ends are cropped off. Then the bars are heated again and rolled to ¼-inch diameter round wire in ten passes, after which the wire is coiled. This hot-rolled wire is then reduced to smaller sizes and sectional shapes by cold rolling and drawing, bull plates and diamond dies being used in the latter operation.

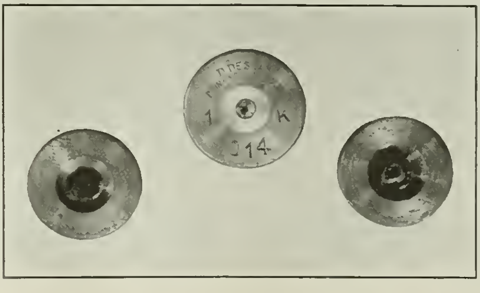


Fig. 1. Diamond Dies used in drawing Chromel Wire

In Fig. 1, three diamond drawing dies in different stages of completion are shown. The diamonds used

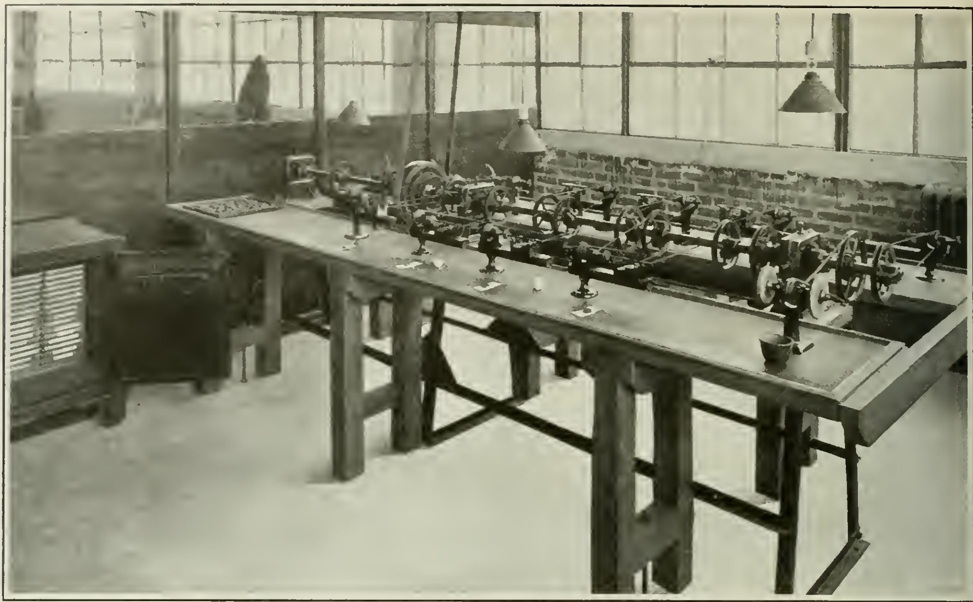

Fig. 2. Corner of the Diemaking Room where the Drawing Hole is lapped through the Diamonds

range in weight from 1/6 to 1/3 of a carat for the smaller sizes of wire up to from 4½ to 5 carats for the larger sizes. Chromel wire that is produced by drawing through diamond dies is not made larger than No. 16 gage (0.051 inch). As the size of the wire increases, the amount of reduction in diameter at each drawing becomes greater. This causes the diamond to be subjected to a greater strain, so that if it is too small it will split through the center of the drawing hole. The amount of reduction per die, as a general rule, is 0.0005 inch when drawing from 0.002- to 0.0015-inch wire; 0.001 inch when drawing 0.005-inch wire; 0.002 inch when drawing 0.020-inch wire; and 0.004 inch when drawing wire 0.051 inch in diameter, which is the largest drawn size. Diamonds that are poor in color or that contain flaws are as suitable for this work as perfect stones, provided the flaws do not interfere with the making of a true drawing hole. Black diamonds are considered best, but the white or Bortz diamonds often give as good results and are much cheaper.

Making the Diamond Drawing Dies

The making of diamond dies for steel wire drawing is work that requires a great deal of care. A description of one method of making these dies was published in November, 1919, MACHINERY. However, a somewhat different and more accurate manufacturing process is required when the dies are to be used for the drawing of chromel alloy wire. The procedure in making diamond dies for this class of work is briefly described in the following paragraphs:

The rough diamonds are set into brass die-holders and temporarily held by means of shellac while a conical center for the drawing hole is being cut. An oxy-acetylene torch is then used to braze around the diamond, which results in filling the hole surrounding the diamond, as shown in the dies to the right and left in Fig. 1. The surface of the brass holder is then ground, to smooth off the brazing so that the die will present a flat surface from which it may be located on the surface plate of a lathe while the drawing hole is being finished. This assures that the hole will be square with the face of the die-holder. A finished drawing die is shown in the center of Fig. 1, the lighter color around the diamond indicating the metal added in brazing.

Finishing the Hole in the Diamond

An installation of a number of bench lathes used both for roughing the holes in the diamonds and for the final finishing work is shown in Fig. 2. At one end of the front bench is located a tool grinder, by means of which the fine-pointed lapping tools are ground to within the extremely close limit of 0.0001 inch that is required. The tools, being common needles, are of such small size that in grinding, a man must wear a magnifying eye-glass. At the opposite end of this bench is shown a tray of diamond dies which are in the process of manufacture; these trays are kept in the safe adjacent.

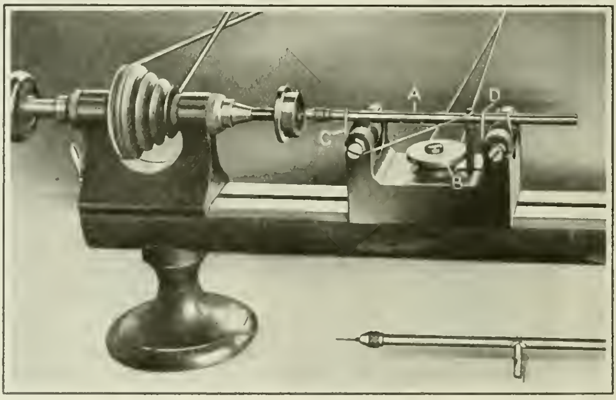

Fig. 3. Set-up of Bench Lathe used in lapping the Drawing Hole in the Diamond

A close-up view of one of these lathes is shown in Fig. 3; here a diamond die is shown centered on the faceplate, to which it is held by shellac. Shellac is

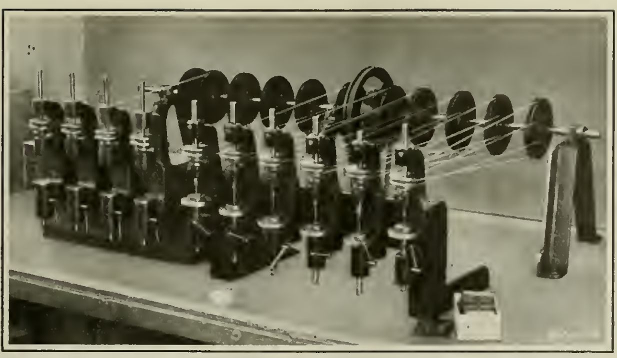

Fig. 4. Multiple-spindle Machines for bell-mouthing both Ends of the Tapered Drawing Hole

a suitable holding medium, as there is no great torsional strain produced while the hole is being lapped through the diamond. The tool used in producing this hole, as stated, is a common sewing needle. The needle is chucked in the end of tool-holder *A* which rests in two V-pulleys supported in the tailstock. The tool is charged with a thin paste of diamond dust and oil, and as the faceplate revolves, the tool-holder moves the needle lap in and out of the hole that is being produced in the die. The reciprocating motion that is imparted to the tool-holder is produced by cam *B* which is driven by a belt from the lineshaft. A vertical post on this tool-holder is held against the cam, and the tool-holder is held down in the front V-pulley by a rubber band *C*. Another rubber band *D* keeps the holder on its seat in the rear V-pulley.

This simple arrangement makes the lapping of the holes through the diamond practically automatic, except for the work of charging the needle lap with diamond dust paste. These machines require so little attention that one man and a helper can easily attend to the nine lathes shown in Fig. 2, and also take care of the machines shown in Fig. 4, while attending to the other work needed in this department. Although the set-up of the lathe appears to be comparatively simple, the required accuracy is maintained, and break-downs seldom occur. The efficiency of the rubber bands is notable; they last for weeks and sometimes months, and if one breaks it can be replaced without delay.

Bell-mouthing the Drawing Hole

The hole produced by the needle lap is tapered and is enlarged at both ends to a slight curve. The wire to be drawn is passed through from the large end of this hole, and the diameter at the small end governs the finished size of the wire and must be held to within limits of 0.0001 inch of the required size. The bell-mouthing is done by the multiple-spindle machines illustrated in Fig. 4.

These bench machines for bell-mouthing the holes are motor-driven, the spindle which carries the needle lap being revolved while the diamond die is held stationary on the platen of the machine. The dies are properly centered relative to the spindle and held in position by shellac. Provision is made for raising and lowering the platen to bring the die up to the needle lap. Directly beneath the pulley on the spindle there is a side cam by means of which the spindle is reciprocated during the performance of the operation. This raises the needle lap on every third revolution of the spindle so that the diamond dust paste, with which the tool is charged, can flow into the hole being countersunk. It will be noticed that the cam is driven by a different belt from that used for revolving the spindle of the machine. These machines are also practically automatic, and after being properly set up they run for hours without further attention.

Drawing the Wire

Fig. 5 shows a machine used for drawing chromel wire. This is a twelve-die machine, five diamond dies *A* being located in the front row and six similar dies in the rear row, the final finishing die being located at *B*. As the drum *C* revolves it draws the wire through the machine from a reel at the opposite end, from which it passes around pulleys, through a tripping lever guide near the floor (see Fig. 6) and over and around rolls *D* and *E*, Fig. 5. Each of the twelve dies reduces the wire in a progressive ratio, until the finished size is produced by die *B*. On this machine the twelve dies reduce the wire size from 0.051 inch (No. 16 gage) to 0.020 inch (No. 24 gage). Obviously, wire can be drawn to any intermediate size by the selection of the proper drawing dies.

The first diamond die through which the wire passes is located in the front row, at the extreme rear. This die reduces the diameter of the wire 0.004 inch, and this amount of reduction decreases with each succeeding die until the reduction produced by the last die in the two rows through which the wire passes is but 0.002 inch. From this die, which is located at the front of the rear row, the wire is passed through the finishing die, which reduces it only 0.001 inch in diameter. The base of the machine is filled with soapy water in which the rolls *D* and *E* revolve while the wire is being drawn, so that both the dies and the wire are thoroughly lubricated.

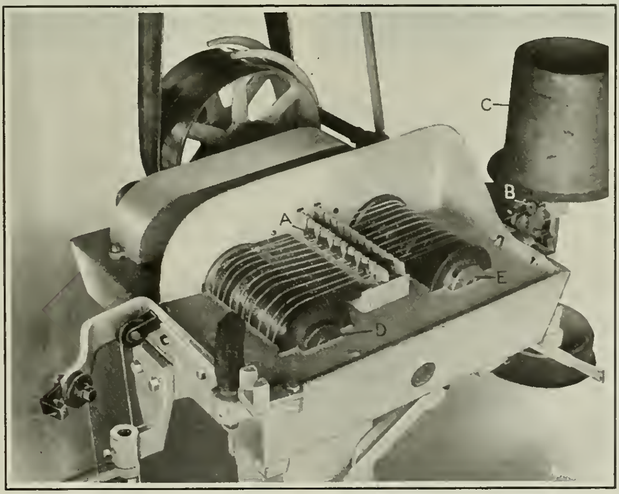

Fig. 5. Wire-drawing Machine, showing Course of Wire during its Passage through the Dies

Another wire-drawing machine of similar construction is shown in Fig. 6, but in this case only one die is used in addition to the finishing die. The tripping mechanism, as well as the manner of passing the wire through a pulley on the tripping lever, is clearly illustrated. Before passing the wire over the rolls and through the dies it is strung from the reel to the weighted lever near the base of the machine. If the wire should become tangled, the tension produced by the drum at the opposite end of the machine will cause the wire to raise this lever, which in turn, will throw out a clutch and stop the machine, preventing breakage. After the wire has been drawn on the machines described, it is made ready for the market by winding on spools. This work is done on automatic machines that wind ten spools at a time. Provision is made on the winding machine for regulating the travel of the rear shaft back and forth to correspond to the length of the spool. The wire is fed on the spool through a holder on this reciprocating shaft, and is thus wound on the spools in even layers.

Rolling Ribbon Stock

Ribbon stock is made by rolling round wire flat in machines similar to that shown in Fig. 7. The ribbon stock varies in size from 0.002 inch thick by 1/64 inch wide to 0.035 inch thick by 1.16 inches wide, and machines of the type shown are used for all sizes. Obviously the larger sizes would require a more powerful machine than that used for the small wire, and when the stock is so heavy that it enters the bar class, it is flattened by hot-rolling. The rolls of the machine illustrated are 4 inches in diameter and 6 inches long, and are made of the best grade of steel that can be obtained. They are properly hardened so that they will not become grooved quickly from the high compressive stresses produced in cold-rolling. The wire thus flattened is rolled to within limits of 0.0001 inch of its specified size on this machine.

The wire must be passed through the rolls at a proper tension, otherwise it will enter the rolls crooked and be fed in jerks. For obtaining the proper tension, the wire is strung from a reel located in front of the rolls around a number of small pulleys and a series of grooved rolls in a more or less zigzag manner. These grooved rolls are located on a plate that is fastened to the machine at *A*, and from these rolls the wire passes between guides *B*, the position of which may be adjusted laterally on the platen so as to enable the entire face of the rolls to be used before it becomes necessary to regrind them. Regrinding is periodically necessary in order to remove the depressions that are worn into the face of the rolls.

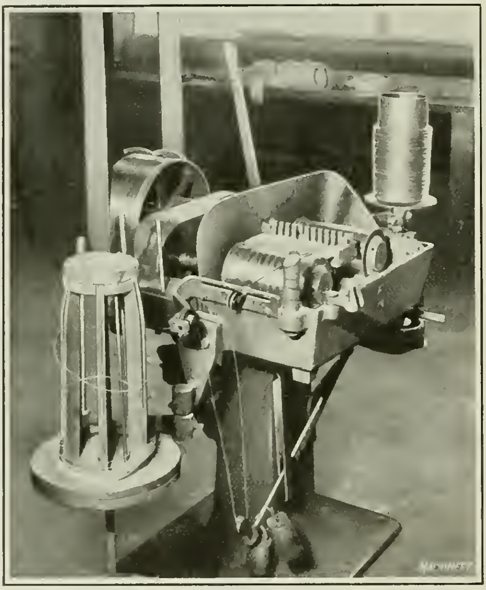

Fig. 6. Another Wire-drawing Machine, showing Automatic Arrangement for stopping

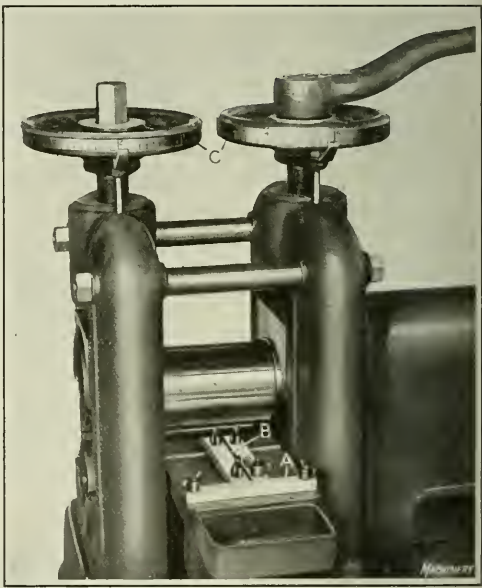

Fig. 7. Type of Machine employed for rolling Circular Wire into Flat Ribbon Stock

Graduated dials *C* enable the top roll to be adjusted to obtain the proper thickness of stock. The graduations on these dials are 1/8 inch apart, and each graduation corresponds to a movement of the upper roll of 0.001 inch so that each end of the roll may be accurately adjusted to bring the face of the top roll parallel with that of the bottom roll. If the rolls are not set absolutely parallel, the ribbon stock will be rolled curved and must be scrapped. In addition to this means for obtaining accurate setting of the rolls, a microscope is always used on the stock itself, which is the most reliable means of furnishing a direct knowledge of its exact thickness.

Machine for Drawing and Winding the Wire Simultaneously

The larger machines used in drawing chromel wire have no provision for winding the wire on spools, but the smaller sizes of wire are drawn and automatically wound on spools by means of the machine shown in the heading illustration. This machine has provision for three instead of two rolls, and fifteen drawing dies instead of the twelve used on the larger machines. The set-up shown in the illustration is for drawing the wire through nine diamond dies, reducing it from 0.2 inch to 0.0015 inch, which is the smallest size in which chromel wire is made. An idea of the size of this wire will be obtained when it is realized that it takes about 212,000 feet or approximately 40 miles of this wire to weigh one pound. One-quarter of a pound, or 53,000 feet of this wire is wound on each spool, and there are seldom more than five breaks in the entire length. Four dies are arranged in each of the rows, as shown, and the finishing die is located at *A*, this die reducing the wire only 0.0005 inch in diameter. If necessary, additional dies up to the maximum of fifteen may be provided, but as many reductions as this are not often made.

The wire is wrapped around the roll *B*, which revolves and produces most of the tension on the wire. The spool *C* on which the wire is wound exerts just enough pull to keep the wire in tension so that it will wind correctly. After traveling around roll *B*, the wire passes up through guide *D* and down around the spool. The shaft on which the spool is carried is given a reciprocating motion so that as it revolves the wire will be wound in even layers. The rate of traverse of the shaft can be regulated to accommodate different sizes of wire.

Difficulties Encountered in Chromel Manufacture

In making chromel wire certain difficulties are encountered that are not met with in making other metals or alloys. Impurities seem to affect this alloy to a greater degree than others. Oxidation, and particularly corrosion, must be guarded against if the alloy is to have a long life at the high temperatures at which it is used. It has been shown by experience in drawing chromel wire that excessive hydrogen in the alloy is responsible for undue breakage. Carbon also makes the alloy brittle, and has to be reduced to traces. Any of the ingredients classed as impurities reduce the heat resistance and electrical resistance of chromel alloy (which are its two most valuable characteristics) and also increase the difficulty of drawing the wire into fine gage sizes.

At one time only pure chromium and nickel were used in making the alloy. However, the chromium need not be entirely free from carbon, as any small percentages contained in it will burn out in the electric furnace during the melt. At first it was thought that electrolytic nickel was absolutely pure, and was therefore most suitable, but it was found that the electrolytic process of manufacture caused the nickel to absorb some hydrogen. This necessitated the use of a small percentage of "shot nickel" for the purpose of reducing the hydrogen of the electrolytic nickel. It has been observed that one English method of making pure nickel, in which the electrolytic process is not used, produces a nickel that is practically free from hydrogen, so that when this nickel enters into the manufacture of chromel, "shot nickel" is not required. This is an advantage, as there is always the danger of introducing other impurities when shot nickel is used.

The iron-chromel must contain the purest iron obtainable, for the inferior grades introduce other impurities that are objectionable, such as sulphur, phosphorus, oxygen, and hydrogen, which are difficult to remove. It may be proper to add in conclusion that this alloy can be readily cast and forged, which adds greatly to its commercial value.

* * *

COMMITTEE ON STANDARDIZATION OF MACHINE TOOLS

Through the cooperation of the American Society of Mechanical Engineers and the National Machine Tool Builders' Association, a committee will be formed consisting of five representatives of the mechanical engineers and five machine tool builders, to work on machine tool standardization problems. The activities of the committee will be carried on under the auspices of the American Engineering Standards Committee, and will relate particularly to the work- and tool-holding parts of lathes, planers, milling machines, drilling machines, grinding machines, power presses and boring mills. Of the representatives appointed by the National Machine Tool Builders' Association, one each will be drawn from one of the groups of manufacturers of the following types of machine tools: Planers; grinding machines; punching and forming machines; machines, using cutting tools, in which the work revolves; and machines, using cutting tools, in which the tool revolves.

Dealers are asked to cooperate by making suggestions to the committee, and the assistance of users is particularly invited, as under the rules of the American Engineering Standards Committee, representatives of three groups must always be consulted in the adoption of standards—producers, consumers, and general interests. Those interested in this matter are requested to communicate either with E. F. DuBrul, general manager of the National Machine Tool Builders' Association, 817 Provident Bank Bldg., Cincinnati, Ohio, or with C. B. LePage, assistant secretary of the American Society of Mechanical Engineers, in charge of standardization committee work, 29 W. 39th St., New York City.

THE INDUSTRIAL ASSOCIATION OF CLEVELAND

Herbert Hoover has said, "A definite and continuous organized relationship must be created between the employer and the employe; by the organization of this relationship, conflict in industry can be greatly mitigated, misunderstandings can be eliminated, and that spirit of cooperation can be established that will advance the condition of labor and secure increased productivity."

Recognizing the value of affording an opportunity for personal contact between industrial employers and employes, aside from their daily contact in manufacturing plants, industrial leaders of Cleveland have established an organization known as the Industrial Association of Cleveland. Its object is educational, the main purpose being to improve industrial conditions. It is believed that the problems confronting industry can be solved by constructive thinking, and it is to stimulate such thought that this institution was founded.

There are two classes of membership, employers and employes. Employer memberships are held by individuals, firms, or corporations, the cost varying according to the number of men employed. Employe memberships cost $5 a year. One of the principles of the association is to keep a balance between the number of employer and employe members. In addition, there is an associate membership for those who are not eligible for either of the full membership classes. Associate members have all the privileges of those in the employer or employe class except that they cannot vote. The membership is open to any employe over eighteen years of age who is interested in promoting industrial prosperity and the ideals for which the association stands. All classes of industry represented in Cleveland are eligible for membership in the association.

Educational Activities of the Association

In line with the educational functions of the Industrial Association of Cleveland, a business training course is maintained to afford an opportunity for instruction in the fundamentals of business. The course for 1922 includes a comprehensive survey of modern business organization and methods. Leaders in their respective fields in the business and professional world have spoken on the following subjects: Economics of business; business plans; finance; organization; plant engineering; advertising; sales and marketing; production engineering; production and control of materials; inspection; shipping; purchasing; accounting and cost finding; credits and collections; commercial law; and maintenance and repairs.

In addition to these lectures, various educational courses are provided to give employe members of the association an opportunity to improve themselves in different departments of business training in which they are interested. For instance, there is a course in stenography, and the business training course mentioned, which has an enrollment of 300. These courses are run on a cooperative basis so that the training is obtained at a comparatively low cost. A number of clubs are also maintained in conjunction with the association, among which may be mentioned the Executives Club, composed of managers and foremen, the Inventors Club, the object of which is to further the interests of men with patentable ideas, and the Faneuil Club, which affords training in public speaking.

The foregoing is by no means a complete account of the activities of the Industrial Association of Cleveland, but it gives a general idea of the work which is being accomplished. In the words of H. B. Bole, the first vice-president of the Hydraulic Steel Co., Cleveland, who is this year's president of the Industrial Association, "The success of the organization is based upon a sincerity of purpose which makes itself actually felt, added to the fact that the organization is based on the sound principle of mutual understanding."

DIRECTIONS FOR USING CHART

To find the horsepower per inch of face width, trace on a horizontal line from the style of tooth desired, to the diagonal line representing the pitch; then trace on a vertical line to the diagonal line representing the velocity in feet per minute; then trace on a horizontal line to the right-hand side of the chart thus obtaining the number of horsepower per inch of face width for either forged steel, cast steel, bronze, cast iron rawhide or micarta.

To find the tooth load at "zero speed" per inch of face width, trace on the horizontal line from the style of tooth desired to the pitch line; then trace on the vertical line to the top of the chart for the tooth load for any of the materials listed.

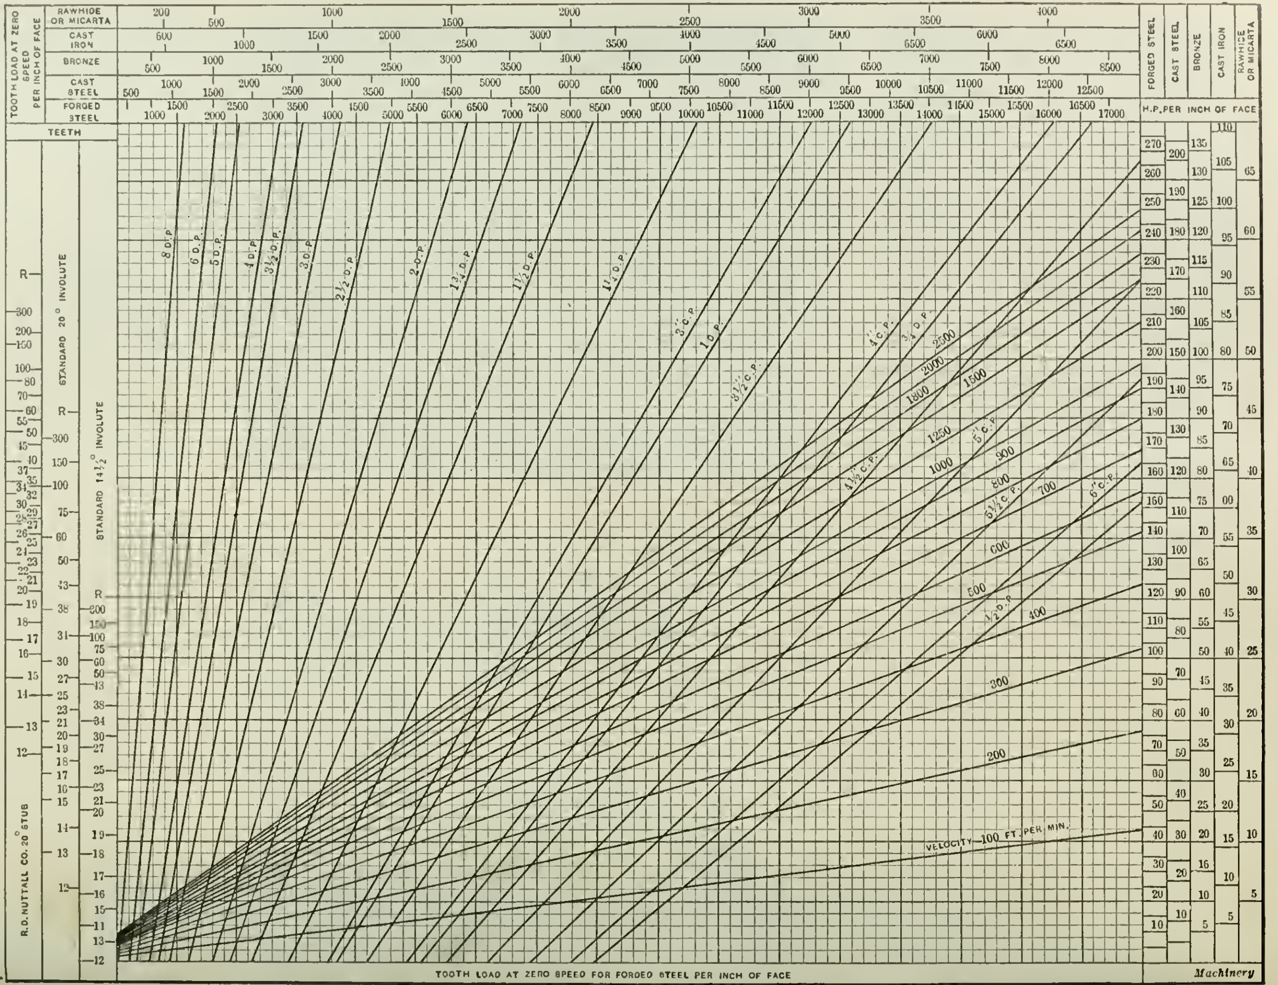

Fig. 1. Chart for determining Power-transmitting Capacities of Gearing and Tooth Loads per Inch of Face Width

Proportions of Industrial Gears*

By G. E. KATZENMEYER, Mechanical Engineer, R. D. Nuttall Co., Pittsburg, Pa.

THE trend of the times is toward more economical and efficient design. A study of the gears in common use discloses wide differences of opinion as to what the engineer considers a suitable design. Evidently if designs can be standardized and a uniform range of sizes adopted, the savings effected in the engineering, pattern, and stock departments and in the shop will be reflected in its costs.

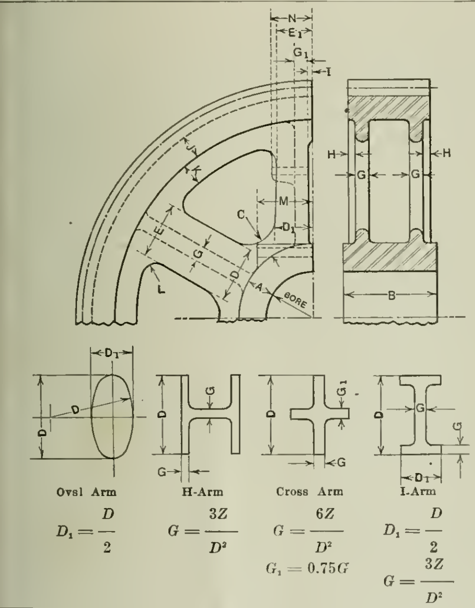
A few years ago it was decided to standardize the design and proportion of industrial gears. Following this decision certain formulas were derived and charts constructed, so that by following a certain procedure, the minimum size of gear for a drive could be readily and conveniently calculated and the sizes thus obtained be inserted on form drawings, without the necessity of making a lay-out on the drawing-board. This was considered desirable when a large number of inquiries were received. When such information as horsepower and revolutions per minute was furnished, it could readily be interpreted and the gear designed, or if the teeth, pitch, and face were specified the design and weight could be determined.

The formulas and charts to be referred to have been developed after a study of various designs and types of gears. What were considered the best proportioned gears were tabulated as to teeth, pitch face, rim thickness, arm sizes and shapes, hub dimensions, etc., and from this information the formulas were derived as a basis for standardization.

In designing a drive to secure the minimum size of gears that can be used, having a sufficient amount of metal under the root of the tooth of the pinion to prevent fatigue and failure, the following method is used: First, calculate the bore diameter of the pinion from the information given, which is generally the horsepower H. P. and revolutions per minute R. The formula used in calculating the bore diameters of pinions and gears is, Bore $= \sqrt[3]{\dfrac{\text{H. P.} \times 80}{R}}$.

This formula is in common use. For general recommendations and for arriving very quickly at an approximate bore, it has proved very satisfactory.

Having thus obtained the size of the bore of the pinion, the next step is to find the minimum pitch diameter which will have enough metal between the keyway and root diameter. To determine the thickness of metal T between the root diameter and keyway, an investigation of a great number of pinions was made, and most of the failures were traced to the inadequate amount of metal above the keyway.



Bore $= \sqrt[3]{\dfrac{\text{H. P.} \times 80}{R}}$

$A = 0.4$ bore or hub diameter $= 1.8$ bore diameter;
$B = 1.25$ bore diameter; (for a gear with a face greater than $1\frac{1}{4}$ bore diameter, make B equal to face; for split gears, make B to suit bolting.)
$C = 0.55A$ or bead diameter $= 2.24 \times$ bore diameter;
$D =$ Dimensions given on chart Fig. 3.
$D_1 = \frac{1}{2}D$ (only for split gears or I and oval arms);
$E = D - \frac{3}{4}$ inch taper per foot;
$E_1 = \frac{1}{2}E$ (only for split gears or oval arms);
$G =$ Dimensions given on chart Fig 3;
$G_1 = \frac{3}{4}G$;
$H = 0.1$ face (only for H or cross-arms);
$I = \frac{1}{4}G$ (only for split gears);
$J = \dfrac{\sqrt[3]{0.5 \text{ No. Teeth} \div \text{No. arms}}}{\text{Diam. pitch}}$
$K = 1.25J$
$L = \dfrac{\text{Pitch diam.}}{4.25 \times \text{No. arms}}$
(J, K, L: See chart Fig. 4)
$M = 2A$;
$N = E_1 + \frac{1}{4}$ inch

Machinery

Fig. 2. Formulas for determining the Gear Dimensions indicated on the Illustrations

From the information collected the formula,

$$T = \frac{\sqrt{\text{No. Teeth}} \div 5}{\text{Diam. Pitch}}$$

was derived, giving the minimum amount of metal permissible above the keyway.

Having the pitch diameter D_p for a certain diametral pitch P, the number of teeth is readily calculated thus: No. teeth $= D_p \times P$. Having the pitch diameter and the revolutions per minute R, the velocity in feet per minute V is obtained by the formula, $V = 0.262D_p \times R$.

Power-transmitting Capacity

Having the number of teeth, pitch, and velocity, the horsepower per inch of face width is found by the Lewis formula.

*Abstract of a paper read before the American Gear Manufacturers' Association's convention, April 22.

Then:

$$W = SP_c Y \times \frac{600}{600 + V} \qquad \text{H. P.} = \frac{W \times V}{33{,}000}$$

where W = tooth load in pounds;
S = fiber stress of material;
P_c = circular pitch;
Y = tooth factor;
H. P. = horsepower; and
V = velocity in feet per minute.

The chart Fig. 1 was constructed from the formulas and is a great help in determining and also in comparing the strengths of different tooth forms and kinds of material. Trace from the tooth column along the abscissa to the pitch line, and then down the ordinate to the velocity line, then along the abscissa to the right and read the horsepower per inch of face width for either forged steel, cast steel, bronze, cast iron, and rawhide or micarta. Multiplying the results obtained by the face width in inches gives the total number

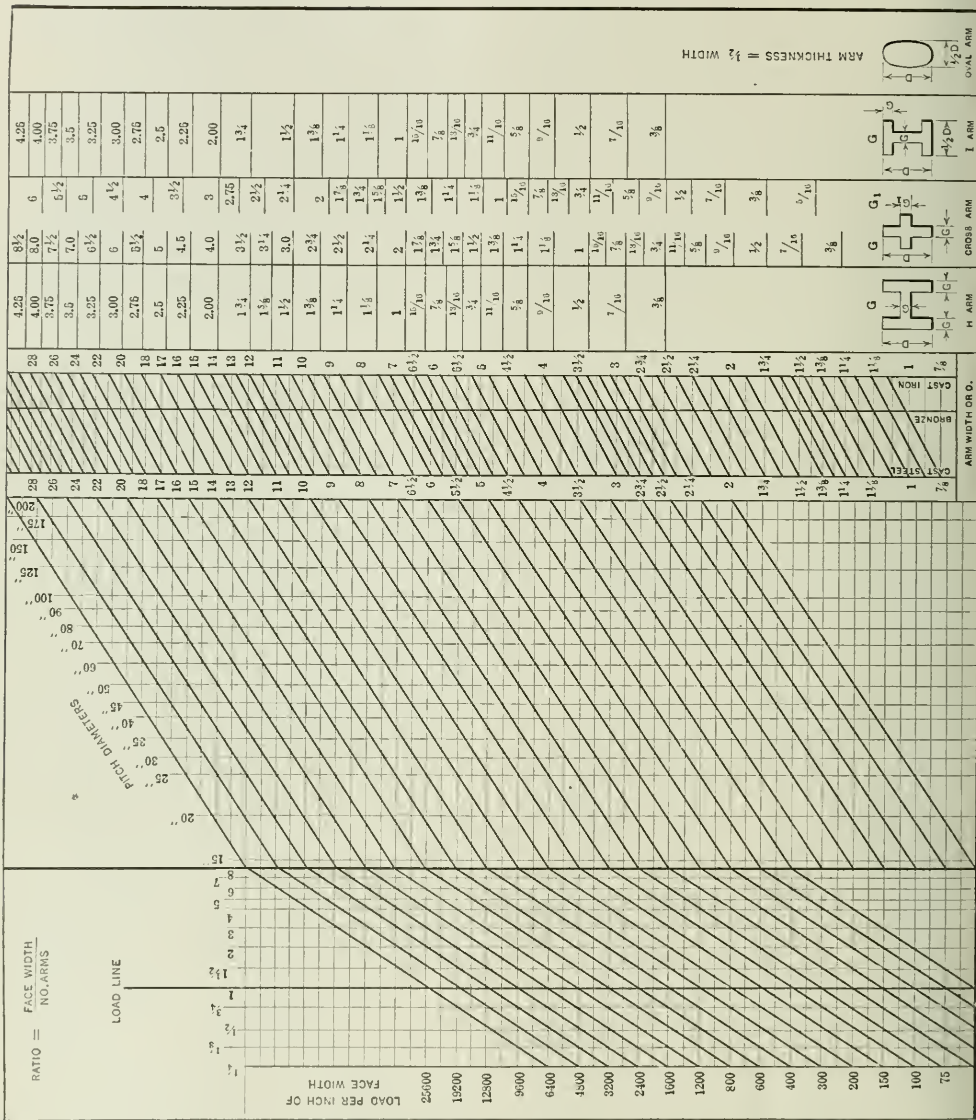


Fig. 3. Chart for determining Widths and Thicknesses of Gear Arms for Different Loads per Inch of Face Width

DIRECTIONS FOR USING CHART

After finding tooth load per inch of face width from the chart Fig. 1, trace from the load line of the accompanying chart, up or down the diagonal line to the ratio of face width to number of arms; then along the horizontal line to the ratio line 8; then up the diagonal line to the pitch diameter, and then along the horizontal line to the vertical line for cast steel, which gives the width *D* of the arm; then trace along the horizontal line to the vertical column representin the style of arm desired (as shown by the diagrams) for other dimensions. If gears are made of bronze or cast iron, trace from the line for cast steel up the diagonal to the line for bronze or cast iron to obtain width of arm; then trace along the horizontal line to the style of arm desired.

DIRECTIONS FOR USING CHART

To find rim thickness *J*, use the left-hand side of the chart and trace from the number of teeth along the horizontal line to the curve representing the number of arms used; then trace on a vertical line to the diagonal representing the pitch; then trace on a horizontal line to vertical line *J* for rim thickness to root circle.

To find height *K* of stiffening rib, trace from line *J* on a horizontal line to the diagonal extending across the center of the chart; then trace on a vertical line to the top or bottom edge of chart, thus obtaining height of stiffening rib.

To find radius *L*, in inches, between arms and stiffening rib, use right-hand side of chart and trace along vertical line from pitch diameter to diagonal representing number of arms used; then trace along horizontal line to the right to obtain the radius.

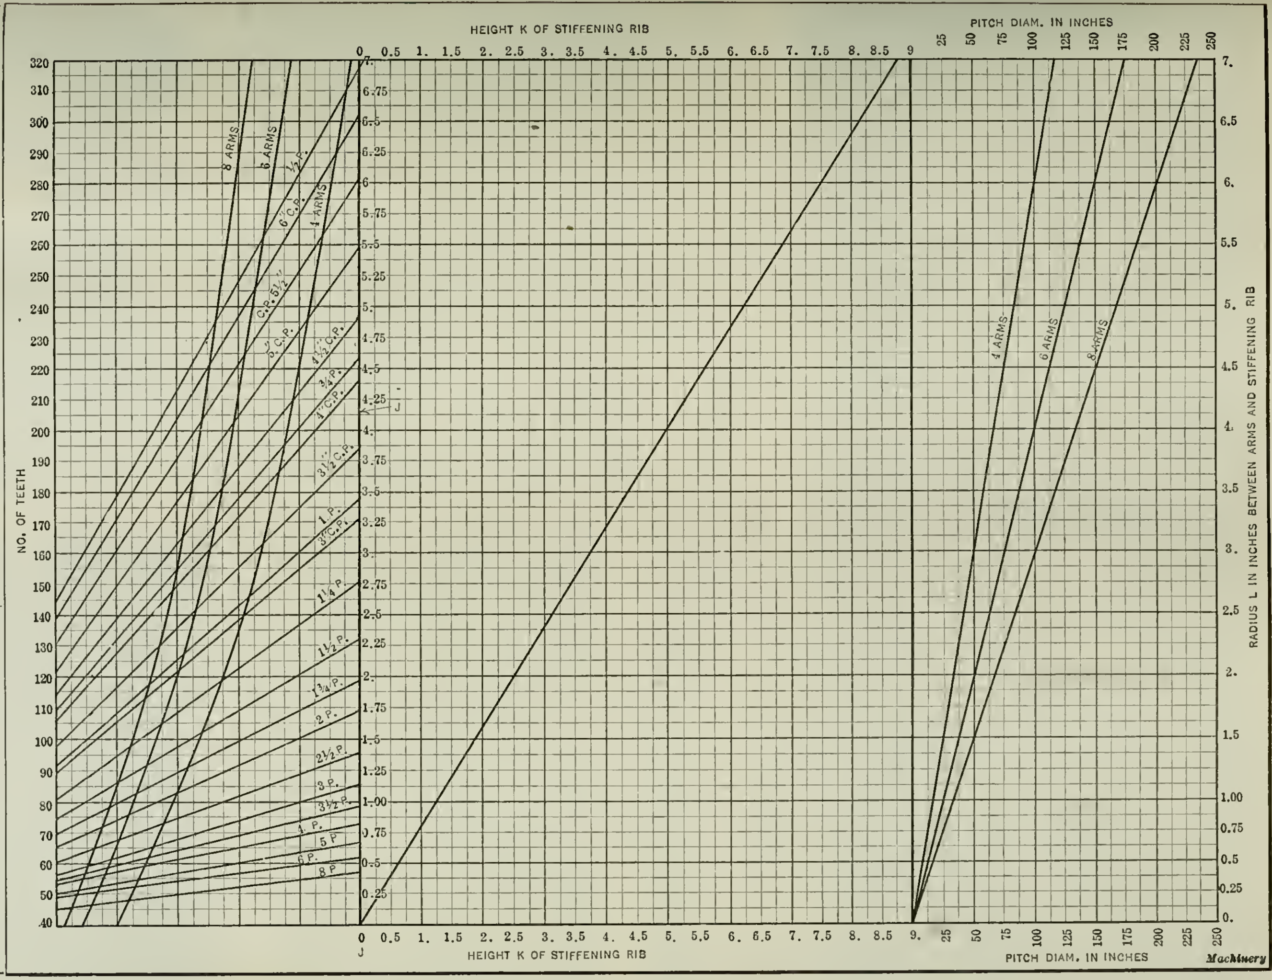

Fig. 4. Chart for determining Rim Thickness J (see Fig. 2) to Root Circle, Height K of Stiffening Rib, and Radius L between Arm and Stiffening Rib

of horsepower. This chart is based on a fiber stress of 20,000 pounds per square inch for forged steel; 15,000 pounds per square inch for cast steel; 10,000 pounds per square inch for bronze; 8000 pounds per square inch for cast iron; and 5000 pounds per square inch for micarta or rawhide.

The face of spur gears is made from three to four times the circular pitch. The minimum face of the helical gears is four times the circular pitch, and the minimum face of herringbone gears is six times the circular pitch. If the velocity factor $\frac{1200}{1200+V}$ is used instead of $\frac{600}{600+V}$ for herringbone or helical gears, the results obtained from the chart can be multiplied by the factor obtained by dividing $\frac{1200}{1200+V}$ by $\frac{600}{600+V}$.

Designing the Gear

After designing the pinion, the gear is designed by using the formulas given in Fig. 2. The bore diameter is determined as previously described in connection with the design of the pinion. Having the bore, the thickness of the hub is made 0.4 times the bore, or the hub diameter is 1.8 times the bore diameter. The hub length is made 1¼ times the bore. If the face is wider than 1¼ times the bore, then the hub length is made equal to the face, except on split gears, the hub length of which is made to suit the bolting, and generally requires a longer hub than a solid gear. The height of bead at the hub is made 0.55 times the hub thickness, or the bead diameter is 2.24 times the bore diameter.

Proportioning the Arms

The next step is the arm design. A six-arm gear is generally used whenever possible in the split and solid type up to approximately 120 inches pitch diameter, and above this size an eight-arm design is recommended. The four-arm design is generally used for split gears under 40 inches pitch diameter with a narrow face and short hub to avoid any special bolting. In calculating the arm sizes, the arm is considered as a cantilever beam with the load equally distributed on each arm. First, calculate for the stalling load or load at "zero speed" which may be found by the formula:

$$\text{Stalling load} = SP_cFY$$

In this formula, F = face width in inches, and the other notation is the same as for the horsepower formula previously given. Having the load, the next step is to find the section modulus of the material, which is,

$$Z = \frac{\text{Stalling load} \times \text{pitch radius}}{\text{No. of arms} \times \text{stress of material}}$$

Having the section modulus, the arm width D (see Fig. 2) is found by the formula

$$D = 2 \times \sqrt[3]{\frac{Z}{0.3927}}$$

This formula is used in calculating the width of all arms and is derived from the formula for an oval section. Let a = ½ width D or the distance from neutral axes to extreme fibers; b = ½ thickness; and $Z = 0.7854\ a^2b$. Then

$$a = \sqrt[3]{\frac{Z}{0.3927}} \quad \text{and} \quad D = 2a \text{ or } 2 \times \sqrt[3]{\frac{Z}{0.3927}}$$

The thickness D_1 of an oval arm is ½ the width D. The thickness of the H-arm section is, $G = \frac{3Z}{D^2}$. The section in this case is considered as a rectangle and the rib joining the two walls is not taken into consideration, as it is intended to give the arm lateral stiffness and not add to the strength in the direction of rotation. The thickness of the cross-arm section is twice that of the H-arm, and the stiffening rib G_1 is made ¾ × G. The width of flange D_1 of the I-arm is made ½ of the arm width, and the thickness of the section is made the same as the H-arm. This arm is used when it is desired to design a gear which will be as light as possible and still be of sufficient strength.

By the use of charts Figs. 1 and 3, the arm sections may be determined readily. On the chart Fig. 1 trace from the teeth along the abscissa to the pitch, then up the ordinate to the load per inch of face for material used. On the chart Fig. 3 use the load obtained from the chart Fig. 1 and trace along the diagonal to the ratio of face width to number of arms, from there along the abscissa to the line marked 8, up the diagonal line to the pitch diameter, then along the abscissa to the material used, and read the arm sizes of the various designs.

The value D_1 = ½D is used with I or oval arms to designate the arm thickness and with split gears as half an arm through the spline at the hub. E is the width of the arms at the rim and is equivalent to D minus ¾ inch taper per foot. E_1 = ½ E and is used with oval arms for the thickness and with split gears as half an arm through the spline at the rim. The H-arms and the stiffening rib of the cross-arm are set back under the rim equal to 0.1 of the face as shown at H, Fig. 2. The amount of relief I from the finished to the rough surface at the spline is made ¼G.

Dimensions of Rim and Stiffening Rib

The thickness of metal J (Fig. 2) between the root of the tooth and rim diameter is equivalent to

$$\frac{\sqrt{0.5 \text{ No. Teeth} \div \text{No. arms}}}{\text{Diam. pitch}}$$

On chart Fig. 4, trace from the number of teeth along the abscissa to the number of arms, then up or down the ordinate to the pitch, then along the abscissa and read the rim thickness. This formula was derived to give varying rim thicknesses, according to the size of the gear and the number of arms used. As a basis, a 100-tooth six-arm gear was considered, having a rim thickness equal to the whole depth of a standard tooth for a given pitch. It will readily be observed that an eight-arm gear with the same teeth, pitch, and face as a six-arm gear does not require the same rim thickness; also that a gear 50 inches in diameter would not require the same rim thickness as a gear 100 inches in diameter, having the same pitch, face, and number of arms.

Height K of the stiffening rib or bead under the rim is made 1¼ times rim thickness J. Referring to the chart Fig. 4, trace from the rim thickness along the abscissa to the diagonal line, then up or down the ordinate and read the thickness of rim bead. Radius L joining the arms and stiffening rib varies according to the pitch diameter and the number of arms, as follows:

$$L = \frac{\text{Pitch diam.}}{4.25 \times \text{No. arms}}$$

From the chart Fig. 4 trace from the pitch diameter up the ordinate to the diagonal representing the number of arms used, then along the abscissa to the right and read the radius.

The height M of the bolt boss at the hub is made equal to $2A$, which is the difference between the hub diameter and the bore. The height N of the bolt boss for the arms is equal to E_1 plus ¼ inch.

When the depth of the keyseat in a hub is checked by measuring across or from the opposite side of the bore, this dimension X may be determined by the formula,

$$X = \sqrt{\left(\frac{Q}{2}\right)^2 - \left(\frac{W}{2}\right)^2} + k + \frac{Q}{2}$$

In this formula
Q = bore diameter;
W = width of keyseat; and
k = depth of keyseat measured at the side.

Although some of the formulas are empirical, the results obtained have been very satisfactory.

Manufacturing Automobile Body Panels

Materials Used in Making Body Panels and Types of Presses Employed

By GEORGE J. MERCER

SHEET steel has come to be used almost entirely during the last twelve years for the panels of automobile bodies wherever quantity production methods are followed. Aluminum is the one other metal used for panels. It is more expensive than steel, but as it is lighter and more ductile, it finds favor where weight is a consideration or where much hand labor is employed in forming the panel. It was these qualities that made aluminum acceptable as the first substitute for wood when automobile bodies made according to carriage practice no longer withstood the severe service to which they were subjected.

Early Use of Sheet Aluminum and Steel

The use of aluminum in the early period increased rapidly throughout the trade, and this demand, together with the needs of other industries, severely taxed the sources from which aluminum was obtained. Consequently, body builders made a practice of ordering their supplies one year in advance, but regardless of this foresight, they frequently had to buy for immediate needs from jobbers who cornered the available supply and charged bonus prices. The unsatisfactory market conditions regarding aluminum compelled the large users to try to find a substitute. A return to wood was not to be thought of and steel was the only other available substitute that could be purchased at a satisfactory price.

Two serious problems faced the pioneer advocates of steel panels: First, there were no large mechanical double-action presses suitable for the work, because similar requirements had never been put up to press builders. Second, with the sheet steel then available it was necessary to heat the metal prior to drawing and forming, in order to prevent it from tearing. Previous work approaching the character of body stampings had been done with dies under a hammer. The metal was also heated in this work, which caused it to scale After such an operation, the scale had to be removed and the part pickled, and much hand labor was involved in finishing and polishing.

The impracticability of continuing under such handicaps resulted in the gradual development of the improved machines and material of the present time. For a short period after power presses were developed for this work, sheet steel was pressed while hot. Present-day accomplishments in any modern stamping plant, such as the cold-drawing

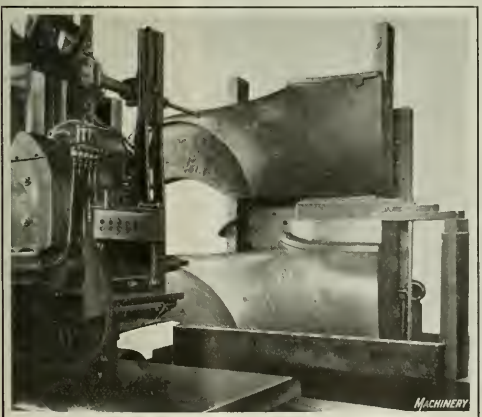

Fig. 1. Machining a Large Die on an Automatic Die-sinking Machine

Fig. 2. Hand Filing a Die after removing it from Die-sinking Machine

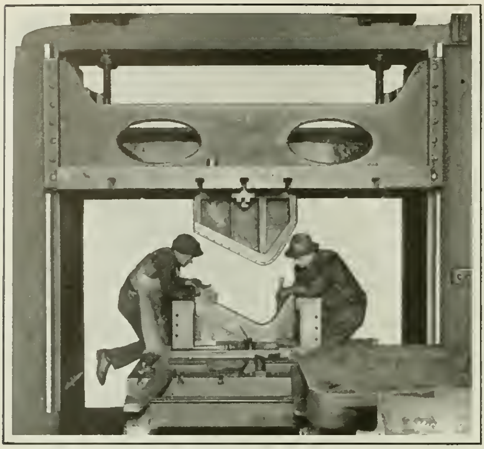

Fig. 3. Matching the Male and Female Die Members of a Set in an Imprinting Machine

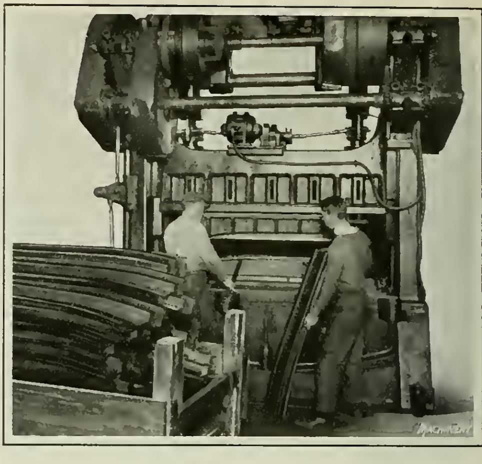

Fig. 4. Forming Two Body Pillar Casings together, which are separated in a Subsequent Operation

of wheel housings from No. 22 U. S. standard gage steel to a depth of 6 or 8 inches in a double-action press, would have been incredible.

Quality and Amount of Sheet Steel Used

The steel used is graded according to the character of the work, and is broadly classed as "automobile body stock." It is a basic deep-drawing stock, pickled, annealed, and refined by cold-rolling so that no roughness or pores will develop on the surface in a drawing operation. This last specification is of the greatest importance because any roughness of the steel will show through the paint. Of course, roughness may be removed by hand-filing, but this represents an additional cost which should be avoided, if possible.

The steel most used for panels is No. 22 U. S. standard gage which is approximately 1/32 inch thick and weighs about 1¼ pounds per square foot. Other steels used, but to a limited extent, are Nos. 20 and 18 U. S. standard gage. The amount of steel necessary for a closed body of the sedan type having a wooden frame and steel panels averages 140 pounds. An open body of the phaeton type requires about 100 pounds. The number of pleasure cars that were built in 1921 approximated 1,500,000, and provided two-thirds of this output had phaeton bodies, this would represent a requirement of 50,000 tons of panel stock. The cost of building a sample phaeton body without painting or trimming, averages $400. In quantities of a thousand and over the same body can be produced at a cost ranging from $35 to $70, the metal work in labor and material in each case representing approximately one-third the cost.

The foregoing figures broadly outline the extent of the automobile body industry. The efficiency of its manufacturing methods depends to a large extent on suitable press equipment for drawing, forming, and flanging the metal in a manner that will leave its surface smooth and true. Hand operations in assembling and finishing are thus reduced to the minimum cost. In the following, some of the methods used in body panel manufacture will be described. The accompanying illustrations were obtained at the plants of the Michigan Stamping Co. and the Clayton & Lambert Mfg. Co., the different examples of press work shown being performed on machines manufactured by the E. W. Bliss Company of Brooklyn, N. Y.

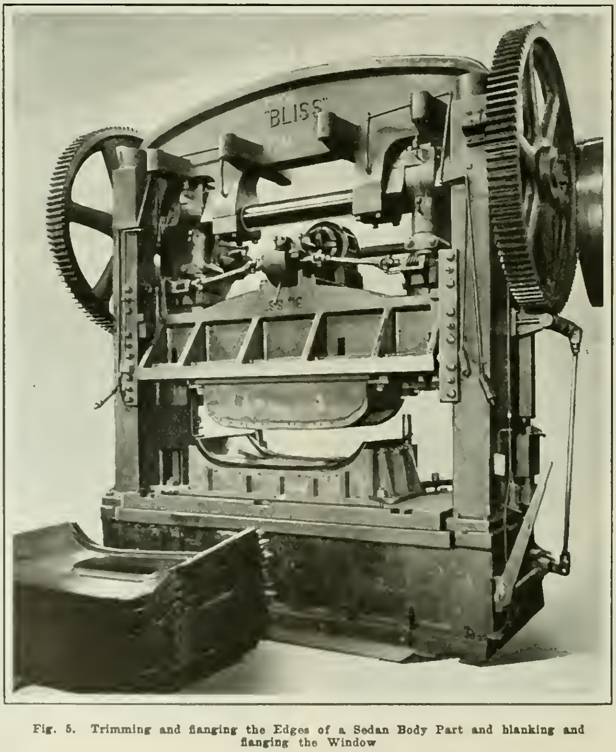

Fig. 5. Trimming and flanging the Edges of a Sedan Body Part and blanking and flanging the Window

The large dies necessary for this work presented a difficult problem at first, as their size and irregular shape made them expensive due to the amount of hand labor involved in making them. The dies are cast, and instead of being filed by hand and ground as formerly, they may now be finished by employing a die-sinking machine. In Fig. 1, a machine built by the Keller Mechanical Engraving Co. is shown finishing the male die of a roadster rear-side panel. This machine is especially designed for handling large forming, stamping, and forging dies.

A master or model above the work and a small roller which registers on the master are utilized to guide the milling cutter on the work. The master can be made either of wood or plaster. As the tracer is moved over the surface of the master, the cutter is moved correspondingly on the casting, with the result that a die that is a facsimile of the master is produced. The tracer touches the master but lightly, so that the surface does not become defaced. However, the tool is held rigidly at every point no matter how slightly indicated by its guide. This machine is electrically controlled through push-buttons. The work can be moved horizontally and vertically, while the cutter has an adjustment for depth. In some instances a two-thirds saving in die cost has been accomplished by using this equipment.

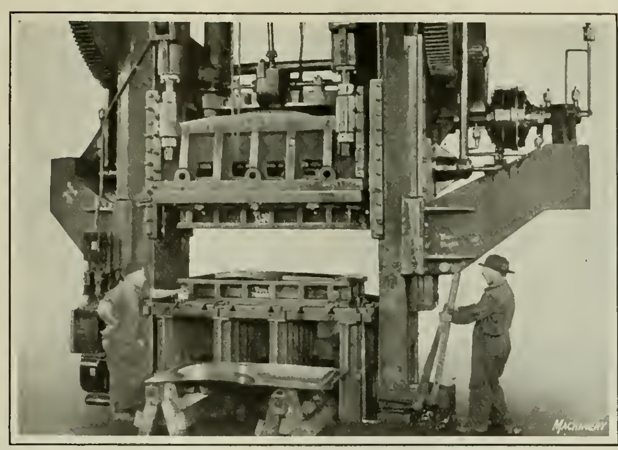

Fig. 6. Toggle Drawing Press with a 9-inch Crankshaft, making Wheel Housings

After the die has been taken from the die-sinking machine, it is hand-filed, as shown in Fig. 2. The final matching of the male and female die members of a pair is performed in the die imprinting machine shown in Fig. 3. This is a machine of recent design which considerably facilitates this work. It affords convenient positions for working on the die, and imprints are easily made. The dies are not taken from this machine until all fitting is completed and they are ready to be set in a press for production. Without such a machine the usual practice has been to hold a press out of production for this work, the imprints being made in the same manner by making a blue mark on one member, then registering the high spots, taking the die out of the press to be filed and finally putting it back for another imprint. Such a method is tedious and laborious, as well as expensive.

The press equipment for making body parts ranges from the large double-crank, double-action toggle drawing press down to the small bench press used in punching nail holes. A typical line of presses of various sizes, all of which are used in panel production, is shown in the heading illustration. The presses used for the major operations are of two types classed as single-action and double-action presses, respectively. Both of these types are of the double-crank style, as often the width of the die bed permits using two dies. Thus blanking and finishing operations can be performed at one downward stroke of the press. In Fig. 7 a large single-action press is shown supplied with two dies, the one at the left being used for blanking and that at the right for flanging.

Single-action presses are used for shallow drawing and forming and for flanging and trimming. They are made in sizes having a crankshaft diameter of from 6 to 10 inches and a die bed usually of from 84 to 124 inches in width, although sometimes the die-bed width is in excess of the latter dimension. When presses of this design are used for forming and drawing, it is necessary to provide additional equipment for holding the metal under pressure. This may consist of spring drawing attachments or pneumatic die cushions. These devices increase the capacity of a single-action press by enabling it to perform, to a limited extent, the same work as a double-action machine. Figs. 4 and 5 show double-crank, single-action presses equipped with spring drawing attachments. The tools in Fig. 5 simultaneously trim and flange the outside of a sedan body part and blank out and flange the window opening. The operation in Fig. 4 consists of forming body pillar casings, two of these being produced from one blank and separated in a subsequent trimming operation.

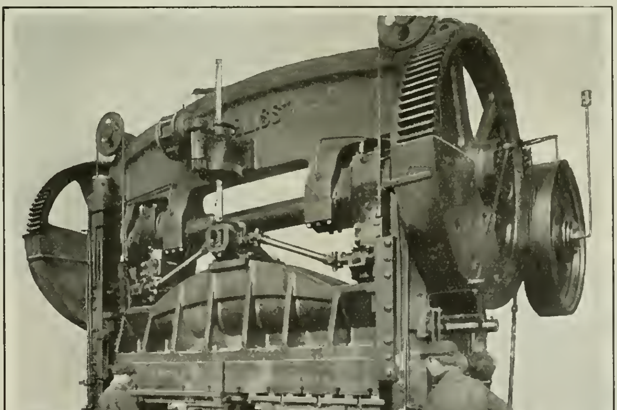

Fig. 7. Large Single-action Double-crank Press used for blanking and flanging a Part at One Stroke

The double-crank, double-action toggle drawing press is used for all the difficult deep-drawing and stretching operations on such work as cowls, wheel housings, mudguards and tonneau backs. Presses of this type are constructed with an inner and outer slide,

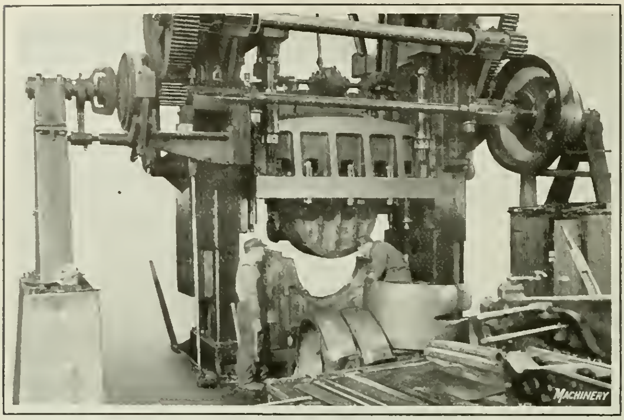

Fig. 8. Another Large-sized Toggle Drawing Press making Mud Guards

and the working tools consist of three members, a lower die, a blank-holder, and a punch. The lower die is fastened to the die bed, the blank-holder to the outer slide, and the punch to the inner or drawing slide. The drawing slide is operated direct from the crankshaft, and therefore has a continuous uniform motion. The blank-holder slide is operated through the toggle mechanism which gives the slide a dwell to hold the sheet-metal blank under sufficient pressure to prevent it from wrinkling or buckling as the punch draws it into the lower die. The amount and distribution of the pressure on the blank means success or failure in deep drawing operations; therefore, blank-holder slides are provided with adjustments so that the pressure may be regulated. The majority of presses of this type have a 9-inch crankshaft which exerts a working pressure of approximately 375 tons. The width of the die bed varies from 86 to 120 inches. There are also some presses with 7- or 8-inch crankshafts, used for door panels, aprons, and other small pieces.

Fig. 6 shows a double-crank toggle drawing press with a 9-inch crankshaft being used to produce wheel housings, and Fig. 8 shows a machine of the same style performing an operation on mud guards. In the latter illustration the operation of pressing a double rear guard has just been completed. Figs. 9 and 10 illustrate two operations on a one-piece cowl. The presses employed are of the same type as those shown in Figs. 6 and 8.

In conclusion, the writer would like to call attention to the warning voiced by those with a varied press experience; that is, when buying a power press, especially if it is to be used for drawing operations, select one with reserve power above the actual requirements. A double-crank toggle drawing press with a 10-inch crankshaft is more economical in the long run for doing the work that a 9-inch crankshaft machine is normally intended for, than a press of the latter size would be. The reserve power of the 10-inch press will give an additional factor of safety and avoid mishaps and breakdowns. A press is subjected to unusual stresses, and the larger machine, having an excess of strength, will not be injured by the overload and consequently will always be ready for continuous production.

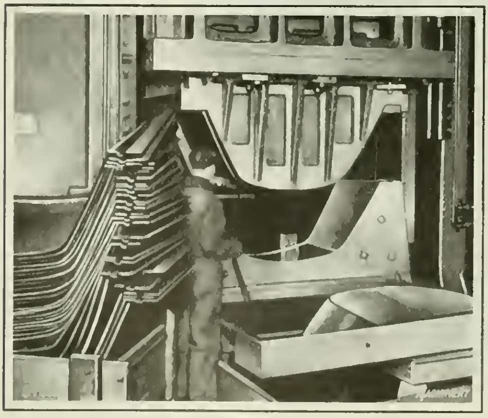

Fig. 9. Close-up View of an Operation on a One-piece Cowl

* * *

The London & Northwestern Railway in England has arranged to make trial runs of a condensing-turbine electric locomotive, which has recently been completed by W. G. Armstrong Whitworth & Co. Ltd., at Scotswood. The locomotive is made up of two engines, the leader being a 2-8-0 type and the trailer 0-8-2. The engines are equipped with four 275-horsepower, three-phase slip-ring motors. Two of the motors drive the leading engine, which also carries the boiler and the impulse-pressure compounded multi-stage turbine and generator. The other two motors drive the rear engine, which carries the condenser, cooling water, and coal. Each engine has eight coupled 4-foot driving wheels, and the total weight is 130 tons.

Fig. 10. Another View of an Operation on a Cowl

* * *

According to the 1919 census of manufactures, there were in that year 4000 factories, with 400,000 employes, engaged in building industrial machinery of all kinds, the production representing $2,200,000,000. Even under the depressed conditions in 1921, the exports of machinery for industrial purposes of all kinds were valued at $254,000,000. Industrial machinery does not include such items as typewriters, sewing machines, etc., not mainly intended for industrial purposes.

Cost Recording and Production Control in Drop-forging Plants

By H. F. OSLER

A system of management that has proved very successful in two large drop-forging plants is described in the following. Before proceeding with a description of the system, a brief analysis will be made of certain conditions in the drop-forging industry that demand the general adoption of more efficient cost-recording systems.

Demand for Accurate Cost Records

Manufacturers in all industries realize now, as never before, the vital importance of a reliable cost-recording system. The conditions of present-day competition are such that contracts must be made at small margins of profit. For this reason, actual production costs must be known and intelligently employed in planning future production and setting contract prices. Unquestionably, a cost accounting or recording system cannot function satisfactorily unless it is closely coordinated with the planning and production control system. The establishment of such a system in a drop-forging plant, however, presents a very difficult problem.

Effect of Inefficient Cost System

In many instances, the manufacturer who cuts his price does so because he does not know his actual production costs, but relies on the ability of his plant to turn out the work at as low a cost as the plant of his competitor can. This practice often results in a contract that cannot be carried out at a profit, and, in many instances, results in an actual loss to the manufacturer. In the attempt to fill such orders or contracts at a profit, quality is often sacrificed. Thus it becomes evident that the manufacturer whose business is conducted on a basis of accurately computed costs has the advantage over his competitor, who can only estimate the approximate manufacturing cost of his products.

Many manufacturers of drop-forgings claim that it is practically impossible to lay out a work schedule in their plants that can be adhered to or successfully followed, and that the processes of manufacturing are such that accurate production costs cannot be ascertained. For this reason, those engaged in the management of drop-forging plants will find the following description of a successful production control system in a drop-forging plant of timely interest. The system to be described owes much of its success to the close coordination that it tends to establish between the production planning, production control, and cost-recording departments or units of a plant.

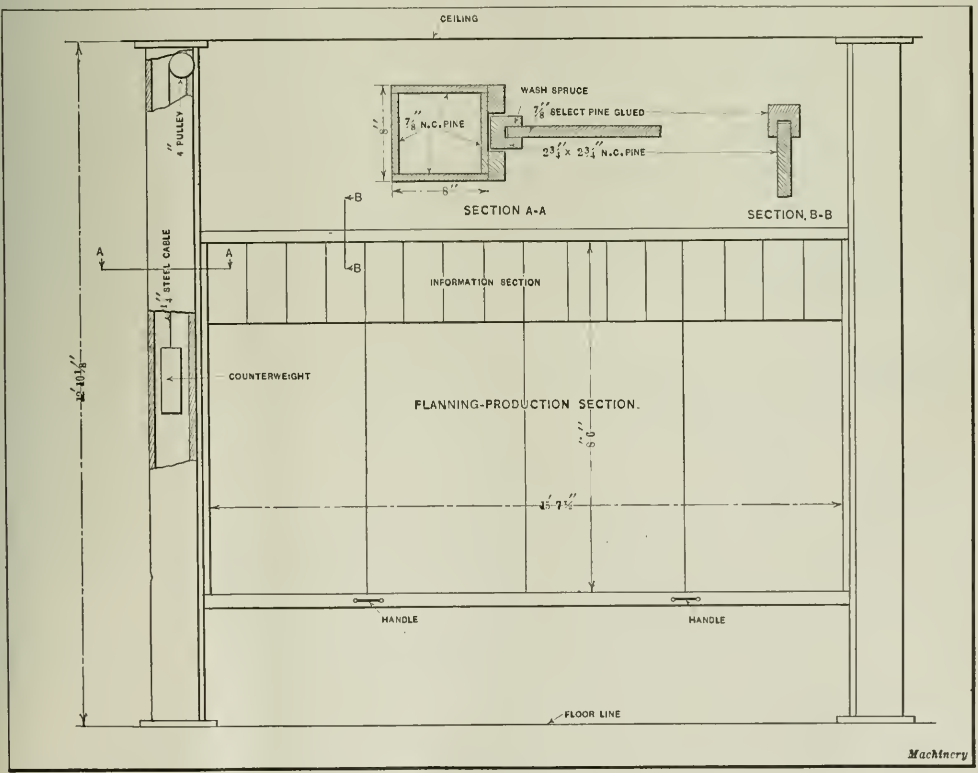

Fig. 1. Information, Planning, and Production Control Board used in the Planning and Production System of a Drop-forging Plant

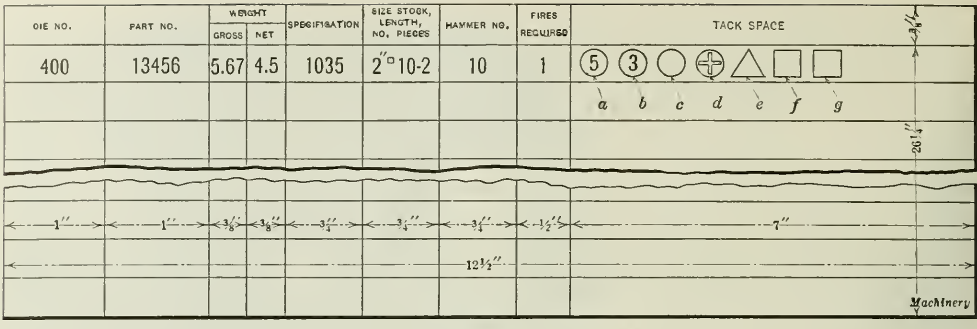

Fig. 2. Information Recording Sheet employed on the Control Board shown in Fig. 1

Production Control System

A simple method of showing graphically the production plans for three months in advance, the existing state of work under way, and the complete history of finished work, forms the basic principle on which the system to be described was developed. One of the most important features of the system is that the collection of data showing the actual cost of each and every individual product is accomplished almost automatically. The system is so carefully worked out in this respect that costs are known at once—not days or weeks after the work is completed.

The Planning and Production Board

The combination information, planning, and production board shown in Fig. 1 forms the backbone of the management system. On the upper section of the board designated "Information Section" are placed the information sheets, one of which is shown in Fig. 2. A board of the dimensions shown in Fig. 1 will accommodate a sufficient number of these sheets for recording the production progress of 100 dies. The lower section of the board carries the planning and production sheets. A section of one of these sheets is shown in Fig. 3. The capacity of this section of the board is sufficient to provide for the production records of the current month and the plans for two succeeding months. When the current period ends, the record sheet is removed and succeeded by the next sheet, and a new one is placed on the board so that the board will carry the plans for practically three months in advance. Thus the progress of work under way and the plans for from two to three months in advance can be seen at a glance.

Information Section

On the permanent information sheet shown in Fig. 2 is placed each die number in its numerical order, and opposite the die number in the second column is placed the number of the part which the die produces. In the illustration, 400 is the number of the die and 13456 the number of the part produced by the die. In succeeding columns are given the gross and net weight of each forging made by the die, the size of material to be used in making the forgings, the length to which the material is cut, the number of pieces each length will make, the number of the forging steel specifications, the hammer for which the die is best suited, and the number of fires and helpers required to make the forgings. Following these columns a space is reserved in which to insert tacks which are used to indicate by their shape, color, or color combinations, all the information required to insure the proper execution of orders for having the stock and dies delivered at the proper place at the right time.

The key or explanation to the tack system of recording information is given in the form of a chart located near the planning board. For instance, the tack at *c* has a round red head, which, according to the chart, would indicate that an order for forgings for part No. 13456 has been received. The tack at *a* has the highest serial number used in connection with this part marked on its head, and the tack at *b*, the serial number then in use or the one last used. Two of these plain tacks on which numbers can be written are required for each die, and they are the only ones that ever bear any written notes or numbers. All the other kinds of tacks employed—forty-three in number—convey the desired information simply by their shape, color, or color combinations.

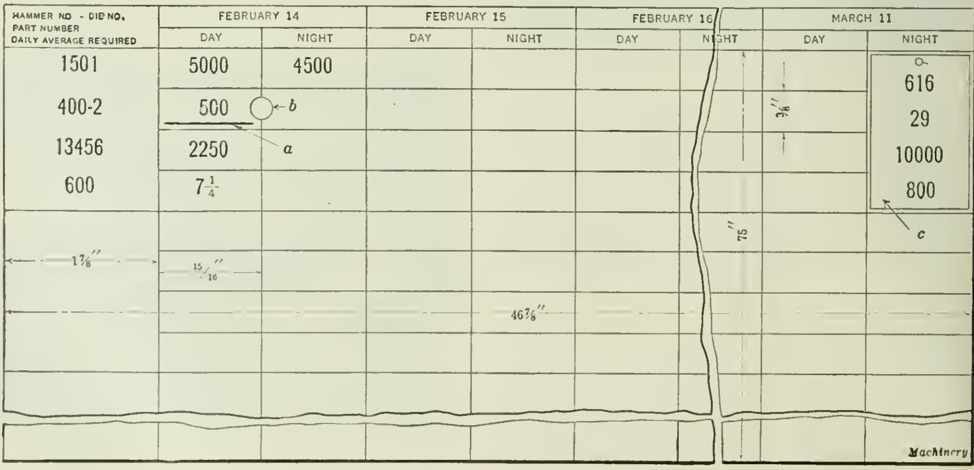

Fig. 3. Production Recording Sheet used on Control Board of a Drop-forging Plant

That is, some of the tacks for a certain class of information will be round and of a solid color, while others may have crosses or bars of a different color.

Still other tacks such as those used for recording information regarding dies or forging trimmers may be square or triangular in shape. Information which must be recorded in connection with all orders is represented by tacks of the more common colors. Considerable attention has been given to the selection of the colors and shapes for the tack heads in order to make the system as easily understood as possible.

Round-headed tacks have the following meanings: When solid red color, orders for forgings; blue, ship freight; pink, ship express; slate, ready to ship; heliotrope, orders held up by customer; black with white cross, steel available; black with white T, steel shipped; black with white horizontal bar, steel ordered; turquoise, hot trim; lavender, cold trim; orange, to be hot restruck; black, to be cold restruck; (square instead of round) slate, to be squeezed; (round) white, to be ground; green, to be pickled; brown, to be tumbled; yellow, to be heat-treated. Square-headed tacks have the following meanings: blue, dies being sunk; yellow, dies to be resunk; brown, dies to be repaired; orange, dies being repaired; green, dies ready for production; white, lead away for approval; red, lead approved.

Triangular-headed tacks have the following meanings: blue, trimmers being made; yellow, trimmers to be made; orange, trimmers being repaired; brown, trimmers to be repaired; green, trimmers ready for production; slate, trimmers scheduled; black square-headed tack, dies scheduled. Round tacks with a dot at center have the following meanings: Red, restriking hot; blue, restriking cold; white, squeezing; green, grinding; brown, pickling; black, tumbling; yellow, heat-treating; orange, forging; turquoise, trimming hot; lavender, trimming cold.

While a large variety of tacks seem to be required, the individual meaning of each can be memorized in a surprisingly short time. Ordinarily, it is necessary to use only a comparatively small number of the different kinds in order to record all the desired information, as the work generally follows a regular course. The presence of a tack in a board of a kind not commonly used immediately calls attention to some break in the usual procedure, and therefore holds the executives attention until the work is again progressing along normal lines.

The hammer numbers are placed in their numerical order on the production sheet shown in Fig. 3. Directly under the hammer number is placed the number of the die which is to be employed at the beginning of the period. Under the die number is placed the symbol or part number and the number of forgings that constitutes a day's work. At the top of the next column is placed the number of forgings required. At the close of each shift, the production department places under this quantity the number of forgings made during that shift. The difference between the number made and the number required is then placed at the head of the next column. This method of recording is continued until the order is completed.

Under the number of forgings made, is placed their total net weight, and under this the hours actually spent in making the forgings. Under the number representing the day's production is drawn a line, such as indicated at *a*, which shows by its color the reason for the delay in production. For instance, a red line signifies that a delay was caused by hammer trouble; a white line, that a delay was caused by absence of the operator; a blue line, die or trimmer troubles; a yellow line, trouble with steel; a black line, power troubles; and a green line, furnace troubles. After the day's production, is inserted a tack *b* which indicates by its color the progress made. For instance, a red tack indicates that production is behind schedule for that particular shift; blue, that production is up to schedule time; yellow, that production is ahead of schedule; black, that production schedule cannot be met.

Opposite each hammer number and under the date on which a new die is to be placed in the hammer, is pinned a ticket *c*, giving the die number, part number or symbol, quantity of forgings to be made, and number of forgings constituting a day's work. This method of recording production plans is carried out for three succeeding months, that is, a new sheet is put up at the end of each month when the sheet carrying the records of the current month is taken down.

This concludes the first installment of this article; the second installment which will appear in July MACHINERY, will describe the actual operation of the system outlined in the foregoing.

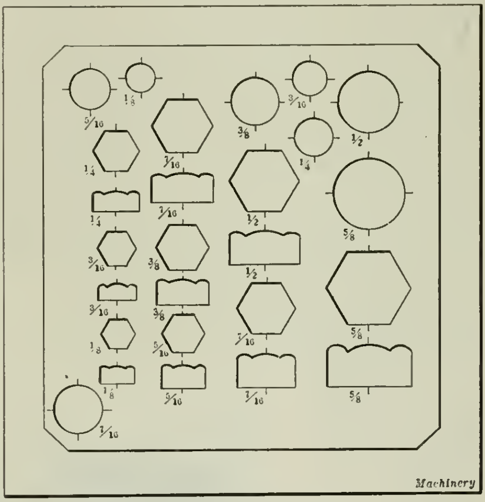
DRAFTING TEMPLET

By G. EDWARD PORTER

The writer read with interest the description of the Lopez "Draftsquare" on page 331 of December, 1921, MACHINERY. In the accompanying illustration is shown a similar device. About seven years ago the writer made up twenty-four of these templets from celluloid 0.015 inch thick. While the templet described in December MACHINERY and the one here shown are obviously intended for the same purpose, it will be noted that their arrangement is somewhat different. One of the twenty-four templets referred to is still used by the writer and is in as good condition as when new. In using the templet, it is understood, of course, that regular center



Templet for drawing Nuts and Circles

lines must be drawn in order to provide a means of locating the device.

In drawing the plan view of the head of a ½-inch nut the circular opening in the templet designated as ½ is centered over the intersecting center lines on the drawing by means of the four lines equally spaced about the opening. The opening is then used as a guide for tracing a circle which will have a diameter equal to the dimension across flats of a ½-inch nut. The templet is next slid over the drawing until the hexagonal opening designated as ½ is in such a position that its six sides are tangent to the circle. With the templet in this position, the outline of the nut can be readily drawn by using the hexagonal opening as a guide for the pencil. In order to facilitate the drawing of threads, the writer cut suitable notches into the edge of the opening in a 30–60 degree triangle. Before cutting the notches, care was taken to make the edge of the opening parallel with the outside edge.

Making Radio Parts

By FRED R. DANIELS

Typical Examples of Screw Machine and Press Operations Employed in the Manufacture of Wireless Equipment

THE methods used in the manufacture of radio apparatus are quite simple, and reveal no startling developments; but the manufacture of radio instruments has grown so rapidly that it has assumed the proportions of an independent industry. For this reason a description of the more important phases of the shop work in this field will prove of interest. This article deals with screw machine and press work in radio shops, the examples having been selected from the practice of well-known manufacturers in the radio field. They are typical of the class of work required to produce wireless receiving sets. Before describing the manufacturing methods, it will be well to mention the parts used in radio receiving sets. Satisfactory sets of this type, using single-circuit equipment, require six units as follows:

1. The antenna or aerial which absorbs the radio waves in the atmosphere and delivers the electrical pulsations to the receiving instruments of the radio equipment.

2. The inductance or tuning coil which is the means of adjusting the wave length of the receiving apparatus to correspond with that of the transmitting station. This unit may be in the form of a plain tubular winding *A*, Fig. 1, or it may be made with a special winding known as a "honeycomb coil," as shown at *B*.

3. The detector which may be either a suitably mounted galena (lead sulphide) crystal *C*, or for higher efficiency, a vacuum tube *D*. The detector changes current from radio frequency—100,000 or more pulsations per second—to frequencies which can be transformed into sound waves.

4. The condenser which is used in conjunction with the inductance or tuning coil to obtain a finer adjustment of the incoming radio waves than is possible with the tuning coil alone. A fixed-capacity condenser is shown at *E* and one of variable capacity at *F*.

5. The head telephone receiver which transforms the pulsating current into sound waves; these are of the familiar construction common to wire telephony.

6. The ground connection.

Each receiving set is designed for a certain wave-length range and will handle only signals sent out by a particular type of transmitting apparatus. Electromagnetic waves are produced either by means of a spark, an arc, or an oscillating vacuum tube. All three are used for radio telegraphy, the first sending out damped waves, the second, damped or undamped waves and the third undamped or continuous waves (C.W.). For telephony or broadcasting, the oscillating tube is generally used, but the continuous wave must be "modulated" for the transmission of speech. Consequently, most single-circuit sets are designed to receive speech tones sent out by a modulated continuous wave (M.C.W.) transmitter.

The units of non-regenerative or single-circuit receiving sets, previously described, differ from those used in the regenerative circuit sets. The latter are capable of receiving all kinds of radio communication, whereas the non-regenerative set is capable of receiving only modulated continuous wave (M.C.W.) and the damped wave telegraphic signals. In

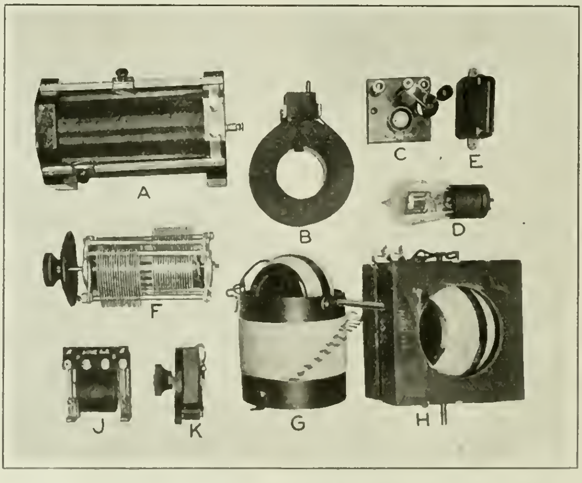


Fig. 1. (A) "Ideal" Tuning Coil; (B) DeForest Honeycomb Coil; (C) Andrea Crystal Detector; (D) Radio Corporation Vacuum Tube; (E) Spitdorf Fixed Condenser; (F) Clapp-Eastham Variable Condenser; (G) and (H) Baldwin Vario-coupler and Variometer; (J) Acme Amplifying Transformer; (K) Radio Corporation Rheostat

the case of the regenerative circuit, the inductance or tuning coil is variably connected by a device, shown at *G*, Fig. 1, which is known as a vario-coupler. The vario-coupler is used for tuning and is connected in circuit with a variometer *H*. The variometer contains a rotor having suitable exterior windings, rotating within the stator which has interior windings and which partially encloses the rotor. The vario-coupler and the variometer together perform the same function in the regenerative type of receiving set that the tuning coils *A* or *B* and the condensers *E* or *F* do in a non-regenerative or single-circuit receiving set. One of the most valuable means for adjusting and controlling the current is the rheostat, which in most types of instruments is of similar design to that illustrated at *K*.

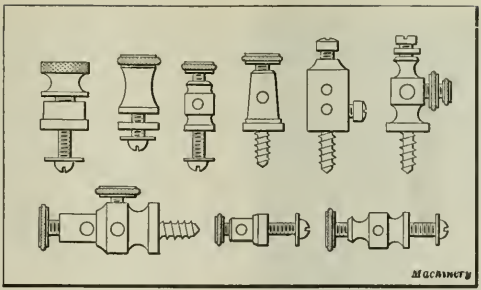

Fig. 2. Various Designs of Brass Binding Posts

In addition to the units necessary for merely receiving wireless messages, it is also highly desirable to include a device for amplifying speech, especially if the transmitting station is so far away that the tones are faint. Almost all commercial tube-detector sets, and even some crystal detector sets, have provision for attaching an amplifier. The amplifier consists of one or more amplifying transformers *J*, connected to the detector circuit and to an amplifying vacuum tube, and a "loud speaker," which is a horn containing a telephone receiver. One amplifier is used to produce what is known as "one-stage amplification"; if a greater volume of sound is required, two or more stages of amplification may be employed.

The vacuum tube forms the most important part of all radio transmitting and receiving sets, except those that operate with a crystal detector. The tube is a glass bulb in which three units are contained—the filament, the grid, which is a coil or mesh of wire surrounding the filament, and the plate which surrounds the grid. This part is clearly shown at *D*.

The collection of radio parts that are illustrated in Fig. 1 was photographed for MACHINERY by the Manhattan Electrical Supply Co., of New York City.

Screw Machine Work in Radio Manufacture

There is a great variety of small screws, washers, contact points, terminal fastenings, binding posts, etc., used in radio instruments. Most of these parts are made of brass and are typical automatic screw machine products. In Fig. 2 are shown a few of the many designs of binding posts—one of the most common screw machine products used in wireless instruments. Another class of screw machine product that is extensively used may be termed "inserts"; these are fastenings, sockets, threaded parts, etc., molded into insulating material such as condensite, bakelite, or formica. The molding of these materials will be dealt with in a separate article, and special attention will be given to the molding of parts containing metal inserts. In the plant of the DeForest Radio Telephone & Telegraph Co., the automatic screw machine work is done on a battery of No. 52 National Acme screw machines, while the Adams-Morgan Co. employs No. 0 Brown & Sharpe automatics.

The variable air condenser, shown in section in Fig. 3, is representative of the classes of machine work found in radio construction. This is a DeForest instrument which consists of a number of hard aluminum plates *A*, assembled in a fixed position, and a number of similar plates *B*, assembled together with provision for turning them to vary their position relative to the fixed plates. The plates may be mounted on the spindle *C* by means of suitable spacing washers, or they may be molded in a lead core on the spindle. These movable plates are operated by a bakelite knob *D* fastened to the spindle. For convenience in making adjustments a graduated bakelite dial *E* is employed. The unit contains numerous examples of screw machine work, such as spacing washers, screws, binding posts, and supporting posts for the two end plates. It also contains good examples of press work, as well as of molded insulator work.

In the manufacture of radio apparatus, use is also made of the hand screw machine or small turret lathe. One example of this class of work is found in the manufacture of vacuum tube sockets in the Adams-Morgan Co. shop. The

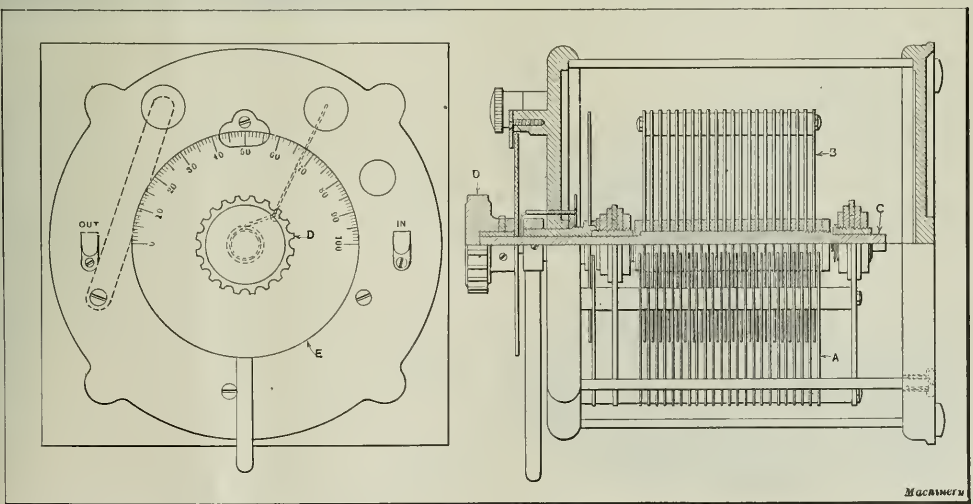

Fig. 3. Variable Vernier Air Condenser used in Radio Receiving Apparatus

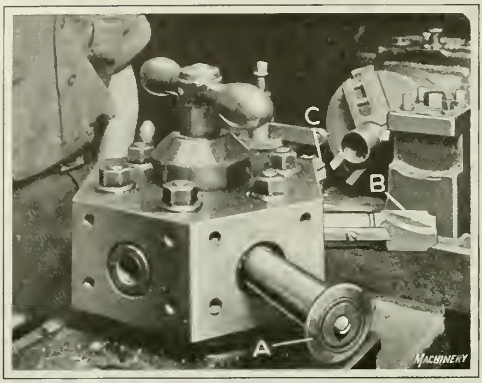

Fig. 4. Turret Lathe used in making Sockets for Vacuum Tubes

sockets are made from 1½-inch brass tubing on a Foster turret lathe, tooled as shown in Fig. 4. The sockets are subsequently molded into a bakelite base, and to help anchor them in the base they are knurled at one end. The operations are: (1) knurling; (2) rough-reaming and forming the end; (3) reaming to size; and (4) cutting off.

The knurling rolls are carried in the front toolpost and the cutting-off tool in the rear tool-holder. The tube is chucked by a three-jaw Union chuck, and the brass collar *A* serves as a stop. For rough-reaming the sockets and forming the end, a special tool *B* is used, to the side of which an auxiliary tool is attached for rounding the end of the tube. A rose reamer *C* is used in the third operation to size the sockets. It may be of interest to add at this time that tube sockets are not always made from brass tubing. The DeForest sockets are molded from bakelite and require no machine work to finish them.

Power Press Work

The tube sockets are molded into a bakelite base, and when returned from the molder they must be polished, plated, and buffed. A bayonet slot, by means of which the vacuum tube is locked in place, is finally punched on a foot-press; this operation is illustrated in Fig. 5. The bakelite base contains molded slots and these are used to locate the bayonet slot properly. The sockets are slipped over a mandrel, and a square-section latch which is hinged to the lower die is swung into engagement with one of the slots

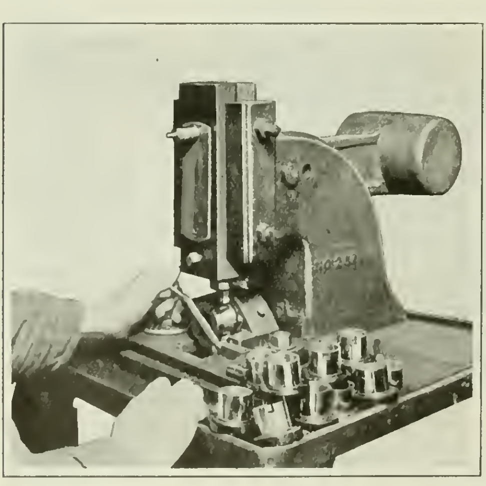

Fig. 5. Punching the Bayonet Slots in Nickel-plated Vacuum Tubes

in the molded base to position and hold the work. The punch, of course, is of the proper shape to produce the L-shaped slot. The thickness of the wall section is 0.065 inch.

Reference previously has been made to Fig. 3 and attention directed to the press work entering into the construction of the variable condenser. The aluminum plates are punched out in dies of similar construction to those illustrated in Fig. 6. The operation illustrated is the punching of the brass end plates for the condenser, the work being performed in the DeForest plant on a V & O press. These end plates are made of sheet brass, 3/32 inch thick, and are punched from strips of sufficient width to permit the stock to be reversed, so that two rows of stampings can be produced from the strip, thus reducing the scrap to a minimum.

Another simple power press operation is involved in making contact points for DeForest inductance coil mountings. One of these mountings, a "honeycomb" coil, and a diagrammatic sketch of the stock from which contact points are punched, are shown in Fig. 7. The mounting is designed

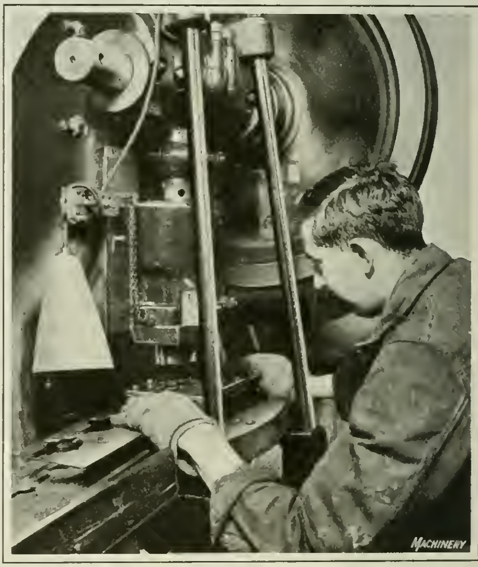

Fig. 6. Power Press equipped with Simple Stamping Dies for making the End Plates of Variable Condensers

so that it may be either attached to a panel or furnished with a suitable base or pedestal for use on a table.

There are three condensite plugs *A*, two of which contain a hinged pin molded in place, by means of which they may swing from side to side. The plugs are also molded with suitable inserts for "plugging in" the coils. The coil is shown in the lower part of the illustration, the plug by means of which the coil is plugged in being indicated at *B*. A spring contact point *C* is assembled to the stud in each of the plugs *A* and *B*, the spring contact being provided to furnish a good connection. The positions of the coils after being plugged into the coil mounting are regulated by means of segment gears *D* which are operated by the bakelite knobs *E*. The middle coil is stationary, the swinging of the side coils varying the "coupling" of the circuits.

At *F* the shape of the spring contacts before forming is shown. These contacts are made from copper, 0.01 inch thick, and the blanks are formed into a thimble shape in two simple press operations. The contacts are punched out with the arms of the star-shaped blank at an angle so that the scrap stock between two punchings may be utilized as spacing washers, thus reducing the amount of scrap. An-

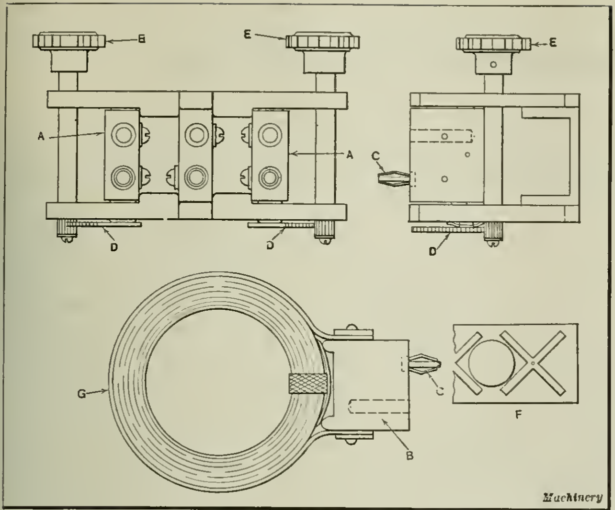

Fig. 7. Honeycomb Inductance Coil Mounting, Assembled Coil, and Diagram of Stock from which the Contact Springs are stamped

other example of power press work in connection with the inductance coil mounting is the punching out of the segment gears *D*, which is done in one operation. The honeycomb coil contains a special winding, and is surrounded by a strip of fiber *G* by means of which it is bound by suitable clips to the plug *B*. Something will be said about the method of winding these coils in a subsequent article, in which several coil windings will be described.

There are comparatively few examples of sheet-metal drawing found in radio work. One of the drawing operations, however, is the forming of the cup in which the galena or other crystal of a crystal detector set is mounted. This crystal mounting contains four miscellaneous examples of press work, which are illustrated in Fig. 8. The cup *A* is made of No. 20 gage (0.0320 inch) B & S sheet brass, and is nickel-plated and buffed. The crystal detector cover *B* is also made from sheet brass, and is nickel-plated, the stock being 0.010 inch thick. The crystal detector ball-sleeve support *C* is made from No. 20 gage phosphor-bronze; this unit is used for producing the universal movement of the contact wire or "cat's whisker." It is necessary, in regulating a crystal detector, to manipulate the contact point until a sensitive spot is found on the galena crystal, and this is done by the use of a ball joint. The crystal holder *D* is made from No. 20 gage (0.0320 inch) B & S stock, and this is also nickel-plated and finished by buffing. These four parts are fairly representative of radio press work other than straight stamping operations.

Pointers for rheostats and control knobs of the type shown at *E* are used in large quantities in radio equipment; these are made from phosphor-bronze and usually assembled to a knob by riveting. The piece of work shown at *F* is a holder for a loud-speaking horn, which is used on the amplifying units of radio receiving sets. This piece consists of a washer punched from flat stock and a threaded sleeve made on a screw machine, the two parts being assembled by spinning.

The use of lathes, drilling machines, engraving machines, tapping machines, and miscellaneous equipment in radio shops will be described in July MACHINERY.

FOREIGN TRADE CONVENTION

The ninth national foreign trade convention held in Philadelphia, Pa., May 10 to 12, attracted a great number of manufacturers and business men from all over the United States. One of the especially valuable features of the convention was the individual advice service in regard to specific foreign trade problems provided for delegates. Appointments were made in advance for those who wished such advice to meet men who were qualified to give them the required information. Among the topics on which advice of this kind was sought and given may be mentioned the following: Financing foreign sales under existing conditions; freight forwarding; contingencies which a marine insurance policy should cover; how to utilize foreign advertising; credit risks and methods of obtaining credit information; preparing salesmen for work abroad; developments in Edge Law banking; the part of the export commission house in foreign sales promotion; how to start an export or import business; protection of trademarks and patents abroad; the use of parcel post for foreign distribution; foreign taxation of American companies and representatives; methods and advantages of forming foreign subsidiaries; relative value of different sales methods; proper use of acceptances; market conditions in various foreign countries; and foreign markets for various commodities. Many papers were read, dealing with almost every conceivable phase of foreign trade. Copies of these papers may be obtained by applying to the Secretary of the National Foreign Trade Council, 1 Hanover Square, New York City.

* * *

The American Engineering Standards Committee has approved as tentative American standard the specifications of the American Society for Testing Materials for cold-drawn Bessemer steel automatic screw stock, cold-drawn open-hearth steel automatic screw stock, methods of chemical analysis of manganese-bronze, and methods of chemical analysis of gun-metal. Copies may be obtained from the American Engineering Standards Committee, 29 W. 39th St., New York.

Power Transmission by Belting

Characteristics of Leather Belting and Charts for Simplifying Calculations

By PETER F. O'SHEA, in Collaboration with Engineers of the Graton & Knight Manufacturing Company

BELTS are rated by the manufacturer as being fit to transmit certain horsepower, but these ratings apply when the pulleys are of equal diameter and the arc of contact is 180 degrees. When the pulleys are of different diameters, the arc of contact is lessened, and it is necessary to decrease the ratings of belts. A wider belt must then be used in order to maintain the desired overload capacity. Any other condition that will decrease the capacity must be carefully considered, as it is necessary to maintain an overload capacity for satisfactory service.

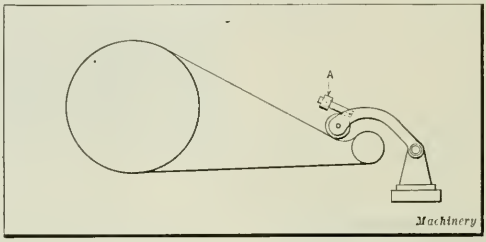

Fig. 1. Swinging Idler on which the Pressure on the Belt may be varied by Means of Weight A

Sometimes the ratings of belts are increased by increasing the arc of contact through the use of idler pulleys, but this practice should be discontinued, as any increased rating above that given for a 180-degree arc of contact is merely a use of the overload capacity of the belt, and, as such, shortens its life. For this reason, the use of idlers in new designs should be abandoned whenever possible. On old drives, however, where the horsepower that must be transmitted has been increased because of additions to the plant, it sometimes seems advisable to install an idler to compensate for the increased load, rather than to go to the expense of installing a new drive.

The method of lacing or fastening the ends of a belt has an important bearing on its capacity. In a test, a belt laced with one of the best types of wire lacing transmitted approximately 15 per cent less horsepower than an endless belt made of the same material and of the identical width. It is therefore evident that belts should be made endless whenever convenient.

Vertical Drives

In vertical drives the arc of contact is often greatly reduced because of the weight of the belt and its stretching under load, which enables the belt to fall away from the lower pulley. When the latter is small and the upper pulley large, a reduction of 50 per cent in the belt efficiency may result, and so a liberal allowance must be made in designing the drive. Failure to observe this point accounts for a large share of the trouble experienced with belts on vertical drives. Thin wide belts have been found to give the best results in drives of this type.

For machines such as power presses, hammers, and planers, on which the load is irregular and shows frequent high peaks, the belt must have a rated capacity equal to the peak load in order to give satisfactory service. In general, to count upon using the overload capacity of the belt for continuous service is to design the drive for a much shorter life than is good practice. On the other hand, while a belt much too large for the work may have an extremely long life, the increased investment involved on the larger belt, as a rule, is not justified.

The coefficient of friction of a piece of leather depends to a large extent on the amount of wear to which it has been subjected. A worn belt which has been well nourished by judicious dressing, and otherwise has received good care will have a higher coefficient of friction than a new one; this shows that the power-transmitting qualities of leather improve with use. A hard-rolled, highly polished belt has a low coefficient of friction and is a poor transmitter of power, while a soft-finished and pliable belt usually possesses a high coefficient of friction.

Relation of Belt Thickness to Pulley Diameter

The type and weight of belt to use on different drives is just as important a consideration as the horsepower rating. In fact, in order to insure that a given belt will transmit its rated capacity, it is necessary that the belt be suitable for the drive. One of the most important factors is the ratio of the thickness of the belt to the diameter of the pulleys over which it must run. This is shown clearly by a test of the horsepower developed by two belts of different weights and thicknesses. In order to obtain a marked difference the motor pulley used was smaller in diameter than the size that would be employed in practice for belts of the thickness used. The belts were new, one being 9/32 inch thick, and the other 1/4 inch thick. They were run from a 4-inch pulley to a 24-inch pulley at a speed of about 1080 feet per minute.

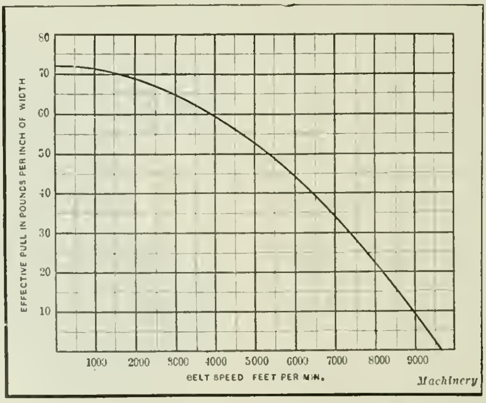

Fig. 2. Chart giving Effective Pull in Pounds per Inch of Width for Single-ply Belts, 3/16 Inch Thick used on Pulleys of Equal Diameter

At this speed the rated capacity of the thicker belt was 14.4 horsepower and of the other belt, 11.5 horsepower. In the test, however, the heavier belt transmitted only 10 horsepower at 2 per cent slip, while the lighter belt transmitted 13 horsepower at 2 per cent slip. Thus, the thicker belt did not transmit as much power as the thinner one, and, in addition, a run of less than one hour of the thick belt caused it to become so hot that it was evidently incapable of continuing for several hours under these conditions without burning seriously and failing on the drive. In the case of the thinner belt, a series of tests extending over several days did not damage the belt in any respect, but rather improved it. These facts show the importance of properly selecting the belt for the drive, as the best belt made may fail utterly if used under unsuitable conditions.

Speed as a Factor in the Selection of Belts

The belt speed is an important consideration in this connection, the heating of the belt being dependent upon the rate at which the belt passes over the pulleys. For this reason, belts running at slow speeds may be safely run over small pulleys, while belts run at high speeds may be unsatisfactory. A belt running at a high speed must be uniform in thickness and well balanced. If a belt runs under little or no load and at a fairly high speed, it will sway from side to side and may run off the pulleys. High-speed belts should not be larger in either thickness or weight than is necessary to carry the load, because when the belt passes around the pulleys and the direction of belt travel is reversed, there is a momentum which must be overcome. This momentum depends considerably upon the size of the belt.

Belts running at high speeds over small pulleys should always be made with waterproof cement, as this material resists the heat generated by the bending and slipping of the belt and does not granulate as easily as ordinary cement. All high-speed belts should also be of the endless type, because any fastener throws the belt out of balance, causing it to flop and perhaps run off the pulleys.

Belts used in damp and wet places, and those exposed to cutting and grinding fluids, should be made with waterproof cement and be waterproof-dressed. Machine oil has a deteriorating effect on belts, and every effort should be made to prevent its coming in contact with belting. When it is impossible to prevent this, a brand of belting should be used which is as nearly as possible oilproof. Certain brands resist the alkali in cutting and grinding fluids, whereas an oak belt would be ruined by it. Oak leather belting should not be run in places where the temperature is higher than 115 degrees F., because the leather is likely to be damaged and the cement softened.

CORRECTION FACTORS FOR DIFFERENT WEIGHTS AND THICKNESSES OF BELTS

Single-ply Belts			Double-ply Belts		
Thickness, Inch	Ounces per Square Foot	Factor	Thickness, Inch	Ounces per Square Foot	Factor
9/64–5/32	12–14	0.8	13/64–1/4	22–26	1.28
11/64–3/16	14–16	0.9	1/4–9/32	26–29	1.44
3/16–13/64	16–18	1.0	9/32–11/32	29–33	1.60
7/32–1/4	18 up	1.1	11/32–13/32	33 up	1.76

Machinery

Belts used on shifting drives should have round edges and possess sufficient lateral stiffness to prevent the edge from curling through contact with the shifter. The same is true of belts running on cone pulleys, and, in this case, the belt should not be the full width of the pulley face; this is a mistake that is commonly made. Shifting belts should also be made endless if possible; otherwise the shifter may catch on the fastener and tear the belt. If an endless belt cannot be used, the ends should be laced tightly together.

Idler Pulleys

As previously mentioned, in cases where a belt is being used in a drive consisting of two pulleys of different diameters, the capacity of the drive may be increased by the use of an idler pulley. The general rule is to place the idler on the slack side of the belt, near the small pulley, so that the arc of contact on the latter will be increased. This arrangement increases the capacity, decreases the slippage, and lessens the tension under which the belt operates. When the tight side of the belt is on top, an idler is of special advantage.

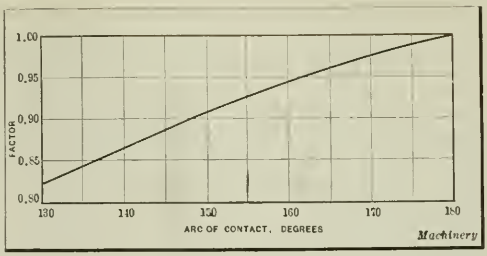

Fig. 4. Correction Factor Chart for Pulleys on which the Arc of Contact is other than 180 Degrees

Screw adjustment idlers are often used successfully, but one trouble with idlers of this type is the danger of imposing an excessive amount of strain on the belt—a point which cannot be too strongly emphasized. Swinging idlers of proper construction cause the belt to wrap the pulleys efficiently, and automatically take up the slack caused by the stretch of the belt under load. They permit the belt to be run very slack, thus decreasing friction in the bearings and eliminating excessive stretch. Idlers of all types must be carefully lined up or they will cause the belt to run off the pulleys. Adjustable idlers are often misaligned through carelessness in making the adjustments, while swinging idlers sometimes work loose and lose their alignment.

An excellent type of swinging idler is shown diagrammatically in Fig. 1. Weight *A* may be varied to take care of different conditions, but should never be excessive. One of the chief advantages of this construction is the short center distance which it makes possible between the pulleys. Such an installation may replace geared, friction, chain, and rope drives. In using any idler, it is necessary to avoid too sharp a bend in the belt between the pulley and the idler, as belts often crack and break under such conditions. A fixed idler pulley is frequently necessary in order to make a belt clear a beam or some other obstruction. In such cases, it is permissible to place an idler on the tight side of the belt, but the action is not that of a true idler. Whenever an idler is used in this manner, it should be looked upon as a necessary evil, since the frictional load on the belt is increased.

Belts running under their rated capacities should have a slight sag on the slack side, which shows that there is no excessive tension, resulting in an unnecessary bearing friction that would cause burnt bearings. Calculations of the capacity of belts are usually based on a low starting load, and if a heavy load is to be applied suddenly, a belt with a high rating should be employed. A high starting torque causes an initial stretch in the belt which cannot be easily calculated. If a tight belt is forced on the pulleys, a crooked spot will develop at the point where it is strained, and a diagonal crease across the belt also indicates that the belt has been too tight on the pulleys.

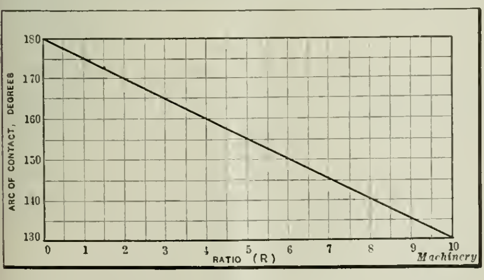

Fig. 3. Chart for determining Belt Arc of Contact on the Smaller Pulley when the Distance between the Pulleys and their Diameters are known

Charts Simplifying Belt Calculations

A number of charts developed by the Graton & Knight Mfg. Co. to simplify the calculations of belt drives are presented herewith. These charts are applicable when the conditions are good and the belt has been well taken care of. The effective pull per inch of width for a single-ply belt, 3/16-inch thick, weighing from 16 to 18 ounces per square foot, may be determined by the chart, Fig. 2, for various speeds up to 9500 feet per minute. This chart is based on the use of pulleys of equal diameter having 180-degree arcs of contact, and so, when the pulleys are of different diameters, a certain correction must be made in the values given. The correction factors for different arcs of contact may be read from the chart in Fig. 4.

Corrections must also be made when the belts are of different thicknesses and weights from those on which the chart in Fig. 2 is based, and these correction factors are given in the accompanying table. The chart in Fig. 3 enables the arc of contact on the smaller of two pulleys to be determined when the diameter of both pulleys and their center-to-center distance are known.

The method of using these charts will be apparent by an example: What horsepower may be transmitted by a single-ply belt, 4 inches wide, weighing 15 ounces per square foot, and running at the rate of 4200 feet per minute over two pulleys, 60 and 12 inches in diameter, respectively, the center-to-center distance between the pulleys being 12 feet? Referring to the chart in Fig. 2 the effective pull for a belt weighing from 16 to 18 ounces per square foot, having an arc of contact on the smaller pulley of 180 degrees and running at a speed of 4200 feet per minute, is found by approximating 4200 on the bottom line of the chart, following a vertical line from that point up to the curve, and then following a horizontal line to the left side of the chart, where the effective pull is found to be about 58 pounds per inch of width.

As the pulleys are of unequal diameter, a correction must be made for the arc of contact, by the use of the chart Fig. 3. In order to use this chart, ratio R must be calculated; this ratio is equivalent to the difference in the diameters of the two pulleys in inches, divided by the center-to-center distance between the pulleys in feet. Thus in the problem under consideration, $R = (60 - 12) \div 12 = 4$. The arc of contact is then found by locating 4 on the bottom line, following the corresponding vertical line to its intersection with the diagonal line and then following the horizontal line at this point of intersection to the left side of the chart. The arc of contact in this case is found to be 160 degrees.

The correction factor for this arc of contact is found from the chart in Fig. 4 by first locating 160 on the bottom line of the chart, then following the perpendicular at this point to the intersection with the curve, and finally following a horizontal line from this point to the left side of the chart. In this case the factor is about 0.94. From the table, the correction factor for a belt weighing 15 ounces per square foot is found to be 0.9. With these values known, the effective pull of the belt per inch of width may be calculated as follows: $0.94 \times 0.9 \times 58 = 49$ pounds.

The horsepower which the belt is capable of transmitting may then be calculated by the formula:

$$\text{H. P.} = \frac{SVW}{33{,}000}$$

in which

S = effective pull of belt per inch of width, in pounds;
V = velocity of belt, in feet per minute; and
W = width of belt in inches.

Inserting the known values in this formula:

$$\text{H. P.} = \frac{49 \times 4200 \times 4}{33{,}000} = 25$$

For a double-ply belt the effective pull determined from the chart in Fig. 2 should be multiplied by 1.6.

[An article published in March MACHINERY, entitled "Charts for Determining Belt Widths" has been criticised on the ground that the belt widths indicated by the charts for transmitting a given horsepower are excessive according to the results of tests and the recommendations of leather belting manufacturers. Wide differences of opinion exist as to the power-transmitting capacity of belts, and the relatively low values represented by the charts previously published are evidently intended to provide belt drives that will reduce, to a minimum, maintenance costs and manufacturing losses due to interruptions incident to belt repairs. According to some investigators, it is economical, in the long run, to use a belt that is wide enough to permit a much lower effective tension value than is usually recommended, the object being to minimize total costs throughout the life of a belt instead of considering largely the initial cost of the belt itself.

While it is true that a comparison of belts operating under different tensions should take into account all losses during the life of each belt, the quality of belting is a factor that must not be overlooked, as it decidedly affects the allowable working stress, permitting higher values for the better grades of belting with the advantage of lower initial costs. It is evident, therefore, that effective tension must also be related to belt quality although this introduces a variable that is difficult to provide for in any general formula.

The power transmitting capacities of belts as determined in connection with the foregoing article are much higher than those given by the charts previously published. We believe, however, that the information given in this article represents approved practice as applied to good leather belting and as determined by recent tests, although apparently even more extensive experiments and tests will be necessary before the power ratings for belts of different kinds and grades are definitely established with reference to all factors that should be considered.—EDITOR]

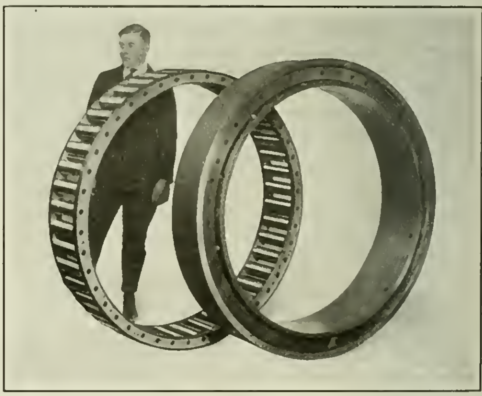
LARGE ROLLER BEARING

The accompanying illustration shows a very large roller bearing recently completed by the Railway Roller Bearing Co., Syracuse, N. Y., for the United States Navy Department. The working load of this bearing is 65,500 pounds, and in testing, it was submitted to a load, while rotating, of 90,000 pounds, and to a static load of 113,500 pounds. The bearing is assembled from 44 rollers, each 10¾ inches long and 3 inches in diameter. The width is 13¾ inches; inside diameter, 49 inches; and outside diameter, 59½ inches.



Large Roller Bearing having a Working Load of 65,500 Pounds

The National Safety Code Committee of the American Engineering Standards Committee has changed its name to the Safety Code Correlating Committee. This committee gives out all national safety codes to the sponsor bodies. The sponsor bodies form representative sectional committees to handle their codes, the personnel of which must be approved by the American Engineering Standards Committee.

Testing Gear and Gear-Cutter Teeth*

By RALPH E. FLANDERS, Manager, Jones & Lamson Machine Co., Springfield, Vt.

THE screw-thread comparator was devised by Mr. Hartness, president of the Jones & Lamson Machine Co. for testing screw threads. The original invention related particularly to a special means of supporting the screw between a source of light and a projection microscope, and a special chart with tolerances indicated on it to receive the projected image. The combination of these novel elements made it possible to inspect all the significant dimensions of a screw thread at a single glance, indicating the degree of error in outside diameter, pitch diameter, root diameter, form, lead, quality of finish, etc., and, more important still, the total effect of all these errors on the fit of the screw in a standard hole for any desired length of engagement. Since some of the elements are common to both thread testing and gear testing, the machine will first be considered briefly as a thread-testing apparatus.

An arc lamp is used ordinarily as a source of light. Its brilliance permits the apparatus to be set in any suitable dimly lighted location, a completely dark room being desirable but not necessary. The small area of the light source also adds to the sharpness of the image—a prime requirement where accuracy is desired. The microscope is of a special construction, the problem solved in this microscope being that of getting a magnification of 200 diameters at a distance from the operator of about five feet, without chromatic diffusion (that is to say, without having the edges of the image show wide bands of color instead of clear, sharp black and white), and without measurable distortion.

Now it is easy enough to meet these requirements if the screen or chart is permitted to be forty or fifty feet away. It is likewise easy enough to get the magnification at close range and with a sharp outline if we do not care about distortion; or with an undistorted image if we are not troubled about hazy color bands instead of a sharp edge to the shadow. But to get all three conditions of nearness, sharpness and accuracy of image is very difficult. The writer believes this result has been attained in this microscope to a degree hitherto unknown.

The machine is a comparator as its name indicates. The final standard is not the outline on the chart, but the plug gage whose shadow is set to coincide with the chart. This principle of using the apparatus as a comparator is followed in the measurement of gear and cutter outlines in that they are ordinarilly referred to an outline on an actual standard instead of to a drawn outline on a chart. The advisability of this will be discussed later.

Fig. 1. Testing Outline of a Gear Tooth, the Image of which is reflected against the Mirror seen in the Background and then forward to a Ground Glass Screen at the Operator's Position

Inspection of Gear-cutters

The simplest application of the machine is for inspecting gear-cutter outlines. The cutter is mounted on a true arbor between dead centers in front of the lens. The microscope, in this case, must have a large aperture to take in the whole tooth. A stop is provided against which the cutting face registers to keep it in the vertical plane for which it is focussed.

Now to get the required degree of magnification (say 90 or 100 diameters for the work) at a distance of five feet, where the operator can observe it and at the same time manipulate the work, would require an angle of projection so wide that no lens system can be devised to preserve both freedom from distortion and achromatism (or freedom from color bands). Therefore the image was reflected against a

*Abstract of a paper read before the American Gear Manufacturers' Association's convention, April 20.

mirror placed at a distance (see Fig. 1) and then back to the operator's position where it is received on the back of a ground glass screen. On the front of this screen the operator can work freely, drawing lines or erasing them, comparing the image with his drawings, etc., all without throwing his own shadow on the screen at the operating position. Another point of equal importance is that a considerable group of men can examine the image at close range without interference.

The mirror is not an ordinary one with a "silvered" or amalgam back, but has an actual deposit of silver on its front surface from which the reflection is made. This is the same method as that used in coating the parabolic mirror of reflecting telescopes. This gives a more nearly total reflection of the light, and above all avoids the double reflection from both front and back faces of the ordinary mirror. The accuracy of the result can be judged from the fact that with a magnification of 100 diameters, differences of 0.0001 inch can be detected.

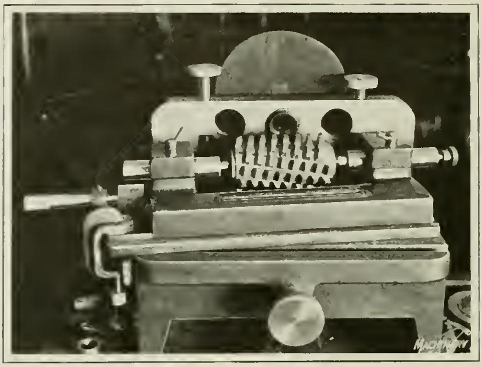

Fig. 2. Hob in Position for testing Accuracy

Testing Uniformity of Form Cutter Teeth

When projecting a form cutter, a most direct and valuable use of the machine lies in testing the regularity of the teeth, one with another. If the outline of the first tooth projected is carefully drawn on the screen, successive teeth may be indexed around into position and compared with the first one. By this means differences in outline may be discovered, whether due to hardening distortion or to inaccurate grinding and also any inaccuracy of the teeth, either sidewise or radial. Furthermore, the teeth of a cutter giving satisfactory results may be compared with one that is not satisfactory and the reasons determined. By reversing the cutter on the arbor it can be seen whether or not the tooth outline is symmetrical. The foregoing relates to the use of the machine as a comparator. The use of this or any other projection apparatus for the direct comparison of tooth outlines with diagrams drawn to an enlarged scale is a more difficult matter—more of a laboratory job than an ordinary shop process.

Testing Accuracy of a Hob

In Fig. 2 is shown a hob mounted for testing on the comparator. The inspection is carried out in somewhat the same way as for a cutter, but, in this case there is the additional element of lead variation to consider. This is taken care of by mounting the hob arbor between centers which are carried by a frame rolling on ball bearings in tracks machined in the base of the device. The advance of each tooth is measured by matching it with an outline on the chart, and reading the axial distance through which it has moved by means of the micrometer or precision measuring blocks, or both.

The center line of the hob must be set at the proper angle to bring the face of the tooth to be inspected as nearly as possible in the focal plane. This angle is presumably the helix angle of the hob, measured at or near the pitch diameter. A stop is used preferably to locate the cutting edge in the focal plane. It should be noted, however, that the stop can be omitted by an expert, as bringing the outline to a sharp focus indicates that it is within less than 0.001 inch of the required position. A movement of this amount either way will blur the outline. This incidentally shows the excellence of the microscope objective.

Method of Projecting and Testing Gear Shaper Cutters

A fixture for projecting spur gears or cutters of the Fellows gear shaper type is shown in Figs. 3 and 4. Fig. 4 shows the fixture with a cutter mounted in place. There is a frame carrying a stud on which the gear or cutter is mounted, and an index-pin or spring plunger carried in a holder adjustable for diameter. This pin has a conical point to engage and locate the tooth space. The stud on which the gear or cutter is mounted is cut away to give two fixed contacts on the side toward the index-pin. In the case of gears with holes varying in diameter, this insures a nearly uniform presenttation of the teeth to the microscope.

When testing the gear shaper cutter (Fig. 4) the following important points should be noted: First, the tops of the teeth are not ground square but at an angle of 5 degrees, so that it is necessary to set the attachment at that angle on the work-table of the machine to bring the cutting edge uniformly into the focal plane. Second, in comparing one cutter with another, due to the nature of the relief on the cutter, the image must be brought to a focus, not by shifting the cutter along the optical axis by the regular focussing screw, but by shifting the cutter along its own axis which

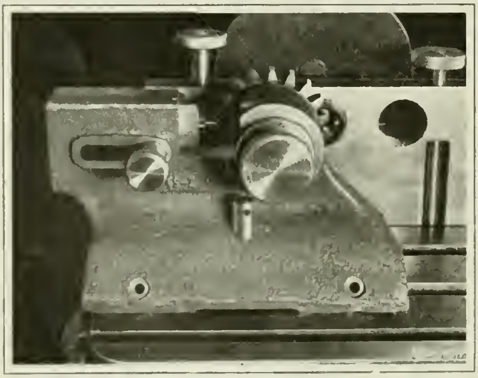

Fig. 3. Front View of Fixture used for projecting Spur Gears or Gear Shaper Cutters

Fig. 4. Opposite Side of Fixture shown in Fig. 3, with Attachment for Gear-testing in Position

is at an angle of 5 degrees with it. Otherwise the comparison will be worthless.

Two kinds of tests may be made with the gear shaper cutter. The first is for indexing. In this test an outline of one of the teeth is drawn on the screeu, and then successive teeth are indexed past this outline and the amount of variation in position is noted. The other, and perhaps more interesting test, is comparing the outlines of the different teeth on the same cutter, or the teeth on one cutter with those of another, or with a standard made for the purpose. In this case the accurate index-pin previously used is replaced by one having a point slightly eccentric. By turning this pin, the cutter can be very delicately rotated to bring the image of each tooth accurately into coincidence with the drawn diagram, irrespective of any slight errors that may occur in indexing.

Besides the precautions previously mentioned, other points inherent in the involute system must be observed. The thinner tooth of the ground down cutter, as compared with a new one, is an essential for theoretical accuracy, and not a mistake. Within certain limits, changes in shape at the fillets, or anywhere below the base circle of the cutter, do not affect the acting surfaces of the cutter or of the gear cut. In the event of an attempt to compare cutter outlines with drawn diagrams, due consideration must be given in this case, as in all others, to the precautions mentioned previously. In this case also the most satisfactory use of the machine is as a comparator, or in other words, as a means of comparing outlines with each other or with a standard, rather than with an unregistered diagram.

Fig. 5. Needle mounted and focussed in Plane to be tested

Fig. 6. Image of Gear Tooth and Needles as seen on Screen

Method of Testing Spur Gears

Projecting cutter outlines is comparatively simple, owing to the sharp, definite nature of the cutting edges, but testing gears is a more difficult problem. The edge is rubbed over on the entering side of the cut and provided with burrs on the other side, which cannot be removed with any assurance that the true outline will be retained. Worse than this, many gears, especially in automobile work, have the teeth chamfered at one or both edges, thus making a reliable outline impossible. Until recently, the best method available was to clamp a thin sheet of metal between two thicker blanks of the same material and cut teeth in all at the same time. This produced a thin templet, which was practically free from burrs and of correct outline, thus being suitable for projection. Theoretically this was all right, but such a gear could not be tested in actual running, nor could it be compared with one that had been run. The problem was thus practically unsolved. What was needed was some method of projecting and tracing the tooth outline on any section from one end to the other. This difficult problem was solved in a very simple manner by Messrs. Beardsley & Porter, of the Jones & Lamson Machine Co.

If a gear with ground, lapped, or otherwise polished tooth surfaces is placed in the fixture shown in Fig. 4, and the device clamped on the work-table so that it makes a slight angle with the optical axis (say, 1 degree) in a direction that tends to display the tooth surfaces to the microscope, an interesting thing may be observed. The diagram on the screen tends to show an outline on the focal plane, whether that be located close to one end of the tooth or somewhere midway. This is due to the fact that the microscope tends to define anything in the focal plane and confuse everything else. Owing to the "thinness" of the focal plane of these special microscopes, the infinitesimal details thus picked out tend toward a sharp outline, but the outline is not sharp enough for practical purposes. How shall this outline be developed?

This was done in a most simple manner. As shown in Fig. 5, a needle was mounted and focussed in the plane it was desired to explore, and then the tooth outline was traced by its point. The junction of the point and its reflection, furnished a location for the surface measurably accurate within 0.0001 inch; and it made possible the rapid drawing of the outline with nearly this degree of accuracy. With the outline once drawn, other teeth of the same gear, or of other gears, can likewise be indicated with the moving needle point, and compared with the drawn outline.

For extreme accuracy, the reflected image of the needle is required, but this does not confine the use of the process to highly polished surfaces. Even roughly cut hardened gears, with the black of the furnace on them, show some reflection under the glare of the arc. The conclusion is that, in general, any ordinary gear will show reflection enough to allow measurement in reasonable proportion to the accuracy of the surface measured.

What promises to be the most practical application of this principle is embodied in the device shown mounted above the index-pin in Fig. 4. A whole battery of needles is laid side by side in the shallow groove of a suitable holder and held in place by a sheet rubber pad which is placed between them and a rotatable spindle (shown in the illustration as a small twist drill). When a gear is mounted in the fixture, and the spindle is revolved between the fingers, the needles approach the tooth outline, stopping in contact with it for its entire length from top to root. Fig. 1 shows the whole apparatus at work, with the inspector in the operating position, and Fig. 6 shows the image on the screen. The appearance of these antenna-like projections and their reflections as they approach each other is weird; but it is satisfying as well, for it represents the solution of a difficult and vital mechanical problem.

The French Machine Tool Trade

By W. P. MITCHELL

THE French machine tool market is decidedly dull. It may be merely "blunt" so far as the French home product is concerned, but the word "dull" is mild when it comes to American or British machinery in the French market. On the other hand, there is an influx of the "made-in-Germany" product, which is penetrating to the utmost corners of France. The small shops using machine tools and equipment, and even the small dealers, apparently care little about the origin of what they buy. Furthermore, capital is not available for modernizing plants with the more expensive American or British product, even though it may be acknowledged to be superior, and many French manufacturers are satisfied if they are able to keep the wheels turning part time without any thought of improvements or expenditures.

Three factors have prevented the continuance of business with America—the abnormal exchange, the increased import duties, and the high freight rates. Certain well-known American manufacturers of machinery in the general field, who have their own establishments in France, have been able to meet the conditions fairly well, but other American manufacturers have found it practically impossible to break into the French market at this time. One firm has become affiliated with a French manufacturing concern, and has been able to do more business than could have been done by selling machinery directly imported from America. This method, however, would not be as applicable in the machine tool field as in the general machinery field.

The solution of the problem is difficult, and there is no likelihood that there will be any improvement in conditions in the near future. The tariff duties will not come down, probably, for years, and it is a question, in view of the French financial situation, whether the value of the dollar will fall materially below ten francs to the dollar. When real peace is established again, the situation may improve, but certainly not before the unsecured paper money becomes a thing of the past.

French Tariff Duties on Machine Tools

The French tariff duties on machine tools, per 100 kilograms (220 pounds), in effect at the beginning of this year, are as follows:

	Country of Origin		
Weight	United States	Great Britain	Germany
200 kilograms or less	50 francs	50 francs	200 francs
200 to 1000 kilograms	24 francs	24 francs	96 francs
1000 to 5000 kilograms	16 francs	16 francs	64 francs

The figures given are multiplied by the coefficient in use at the time of importation, this coefficient being now 3.3. The coefficient may be changed by the administration without legislative action. The tariff on German machines is four times as high as the rates for American or British products; but the transportation charges on the German product are only about one-fifth those on American machinery.

Competition with Germany

Because of present exchange conditions, this is what happens when a machine tool weighing say 200 kilograms and selling for $250 in America is to compete with a similar machine from Germany, which may be priced today at, say, 5000 marks. The American machine will cost the French buyer approximately 3000 francs, while the German machine will cost but little over 1000 francs. Obviously, the Frenchman will buy in the German market if he buys at all, as the figures for the imports of machinery into France in 1921 from America, England, and Germany plainly show. There seems to be little doubt that Germany's financial situation must be improved in the interest of the industrial and trading world everywhere. Competition with Germany in nine-tenths of the European buying market is becoming impossible.

It has been pointed out that Germany is no more formidable today industrially as to ability and equipment than she was before the war, and that the rest of the world found enough to do then and will again. This is true, but an adjustment has to be made first. In the depressing dullness of the French trade in 1921, Germany sent machinery to France exceeding in value by 15 per cent the machinery imported from America, and in tools and other metal appliances, Germany supplied approximately four times as much as the United States, and twice as much as England. Another significant fact is that England sent small tools and other metal appliances to France last year to a value twice that of the imports from America. The following figures give the exact values of French imports in 1921:

FRENCH IMPORTS

	Country of Origin		
	United States	Great Britain	Germany
Machinery and Mechanical Appliances			
Kilograms	65,347,800	55,946,000	71,028,000
Value, francs	331,556,000	385,072,000	386,683,000
Tools and Other Metal Appliances			
Kilograms	5,254,200	13,739,000	20,297,000
Value, francs	28,858,000	52,438,000	104,164,000

Improvement in French Industrial Conditions

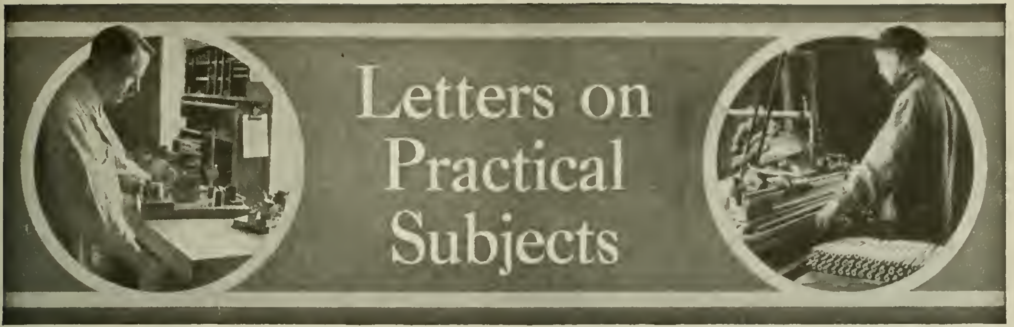
It is true that business in France is improving; at least, production is increasing and, indeed, in 1921, the drop in production in France was considerably less, proportionately, than in either America or England. The increase in the exports of machinery and tools from France to the United States during the last three years is remarkable. The exports of machines, mechanical appliances and tools for 1919, 1920, and 1921 are given below in francs:

	1919	1920	1921
Machines and Mechanical Appliances	1,742,000	5,565,000	16,411,000
Tools and other Metal Appliances	1,304,000	9,563,000	69,304,000

By comparing the import and export figures from the United States into France and vice versa in 1921, we find that the French exports of machinery to the United States amounted to only 5 per cent of the imports from the United States, but in the case of tools and other metal appliances, the exports from France to the United States were almost two and one-half times the exports from the United States to France.

Prospects for the Future

In spite of all, there are reasons to believe that there is a future for the market of American machinery in France. To hold that market, however, courage is required, and stocks must be kept for the occasional buyer; an educational campaign must also be carried on, through which the American manufacturer will some day come into his own. Those manufacturers who are selling to France today—and something must have been sold to account for the 1921 imports valued at over 330,000,000 francs of machinery and mechanical appliances—are those who know the ground, who have tilled it and sown. They will reap, but to do so they must be on the ground at the time of the harvest.



MOLDING BARREL CASTINGS

The evolution of a pattern and core-box for use in the production of large quantities of accurate cylinder or barrel castings is described in this article. The principal dimensions of the casting are shown at *A* in the accompanying illustration. The casting was to have core holes at each end 2½ inches square. It was desired to eliminate all machine work, and it therefore became necessary to hold the castings as close as possible to the specified dimensions.

Probably nine out of ten patternmakers would make the pattern with the parting line through the center, and the 2½-inch core-prints attached to the ends of the pattern as shown at *A*, the core-box being designed to produce half-cores that could be pasted together to form the complete core. A mold made from this pattern would, of course, be poured with the casting on its side in the position indicated at *A*. The first pattern was actually made and used in this way, but it proved unsatisfactory, as the core-prints were not large enough to support the core or prevent it from rising in the mold when the casting was being poured.

The second method tried was molding the pattern on end as shown at *B*. This method was also a failure, because it was very difficult to pass the core down through the mold and enter the print properly in the recess in the bottom of the mold. The end face of the core also proved too small to support the heavy core, so that the latter frequently sunk down into the molding sand.

A slab core, such as shown at *C*, was then provided to overcome this difficulty. The slab core was rammed up in the mold in both the cope and the drag. This prevented the core from sinking into the molding sand, but did not eliminate the difficulty experienced in entering the core in the drag. The core-prints were next cut down to the size and shape indicated by the dotted lines at *b* in view *D*. "Ram-up" cores *a* were made to fit over the prints. These cores remained in the mold and provided a hard surface on which to set the core. The castings produced from this pattern were found to vary in thickness, due to the failure of the cope flask to line up properly with the drag. This method of molding was therefore discarded.

The rather unusual method that was finally adopted with success was suggested by the foreman of the foundry. The pattern was made split through the middle and provided with core-prints attached to each end, as shown at *E*. These prints were made 6½ inches in diameter or ½ inch smaller than the diameter of the body core. The core-prints were given a ¼ inch taper, as shown in the illustration. The

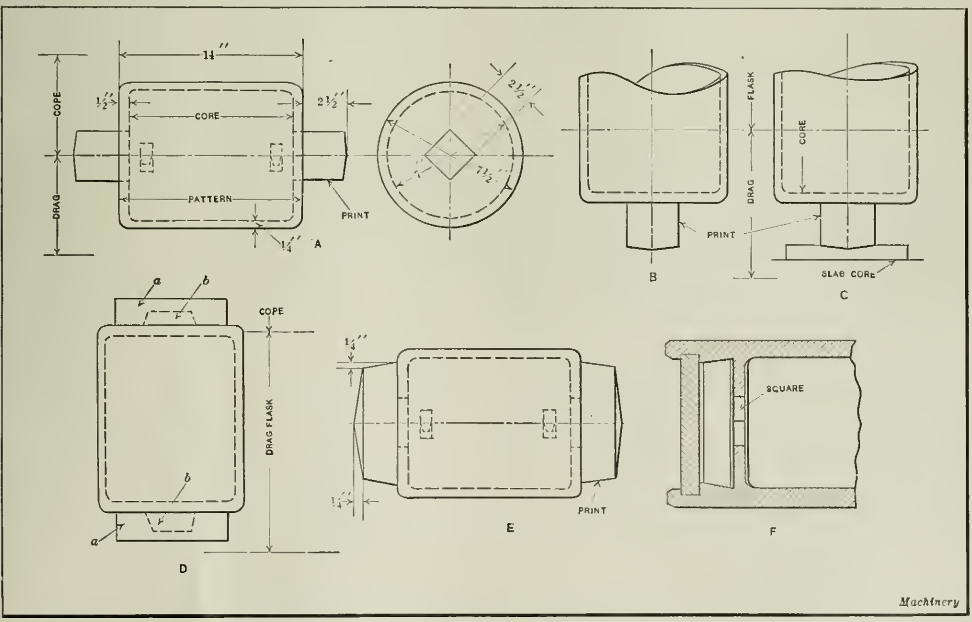


Illustration showing Evolution of a Pattern Core-box for Cylinder or Barrel Castings

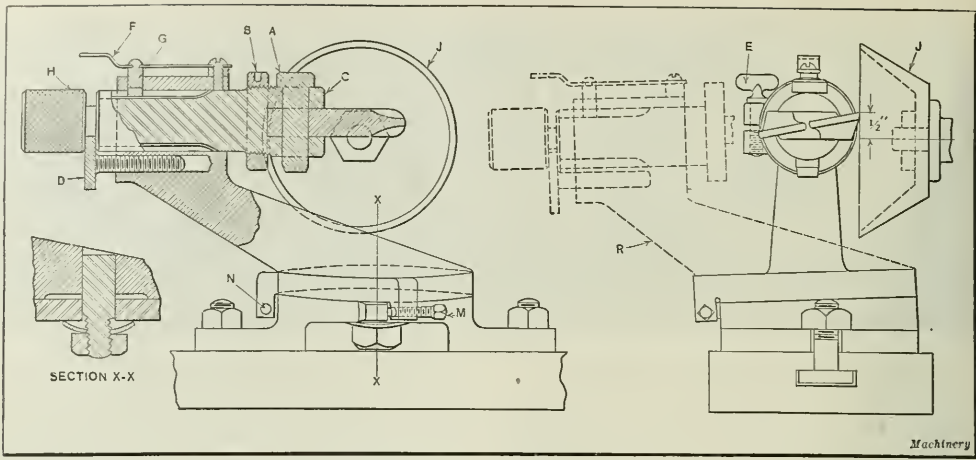

Fig. 1. Details of Reamer-grinding Fixture, a Plan View of which is shown in Fig. 3

core-box for the pattern was made with ends of the shape shown at *F*, particular attention being given to the accurate tapering of the ends of the box. The core-prints attached to this pattern were of sufficient size to support the core properly and hold it in place. With the split pattern and the tapering core-prints, the molder was enabled to mold the pattern either on its side or on its end, as desired.

Kenosha, Wis. M. E. DUGGAN

REAMER AND REAMER-GRINDING FIXTURE

The reamer and reamer-grinding fixture described in this article was designed and placed in successful operation by the writer while engaged as a tool-room foreman in a large shell manufacturing plant. While designed for use in the production of 3.3-inch high-explosive shells, both the reamer and its grinding fixture embody features that can be employed to advantage in the design of tool equipment for various peace-time products.

The reamer, as will be seen from Fig. 2, has a clearance back of the cutting edge of approximately 4¾ degrees. When this type of reamer was first tried out, the grinding of the side and front cutting edges was done on a universal grinder, using a vise to hold the blade. The radius was ground by hand, a profile gage being used to obtain the ½ inch radii. The latter operation alone required about one-half hour. By the use of the grinding fixture shown in Figs. 1 and 3, the total time for finish-grinding was reduced to less than two minutes per reamer. The amount of stock left for finish-grinding was 0.025 inch. The reamer blades were shaped, formed, lipped, the back clearance ground by hand, and the blades hardened before being sent to the finish-grinding department.

The object of the grinding fixture is to hold the reamer in a flat plane while grinding the sides and then to swing it into an angular plane while grinding the radius, this angular position being retained during the grinding of the front cutting edge. As will be seen by referring to Fig. 1, the fixture is provided with a base having an inclined pivot or swivel face upon which swivels an arm mounted on a flat plate. A suitable device for holding and positioning the reamer is mounted on the upper end of this arm. The reamer blade is held in the arbor bar by a pin *A* which passes through a hole in the blade, and a collar *B* which is tightened against the rear end of the blade. The arbor *C* slides through the upper bearing of the arm, and is moved in either direction by a small knurled feed-screw *D*, being locked tight by the thumb-screw *E* acting on the split bearing. The arbor can be indexed 180 degrees, and is held in the two positions by the pin *G* riveted to the spring key *F* mounted on top of the mechanism.

The knurled end *H* of the arbor serves as a handle for operating the fixture. A cup- or deep saucer-wheel *J* is mounted on the wheel-arbor and squared off at right angles to the table, with the center of the wheel about ½ inch below the top edge of the reamer. Stops are provided for grinding the straight side and the radii, and for squaring the end. Referring to Fig. 3, stop *K* consists of a pointer on a sliding member and a stationary plate with a scribed line on it. This indicator is employed when positioning the table for grinding the radii. The radii are ground by swinging the cutter-carrying arm on its pivot base. After grinding one corner to the required radius in this way, the table is fed to the left until stopped by the micrometer stop *L*. During this movement of the table, the cutter-holding arm is at right angles to the face of the grinding wheel, as indicated by the dotted lines at *R*, Fig. 1. Adjustable stops *M* and *N*, which are fitted to the baseplates, limit the rotation of the arm carrying the cutter to an angle of 90 degrees. The accurate location of the diamond used for truing the wheel is of great importance. The point of the diamond must be kept in a line which is parallel with the finish-ground edge of the reamer in order to maintain the accuracy of the set-up. As the reamer is swung around to form the radius and into a position for squaring the end, it is tilted into an angular position in such a way that the portion of the edge in contact with the wheel is always parallel with the wheel-base. A peculiar end-mill effect is produced on the web of the reamer which will cut a clean and perfect center. This end-mill effect is due to the pivoting of the cutter-holding arm in a

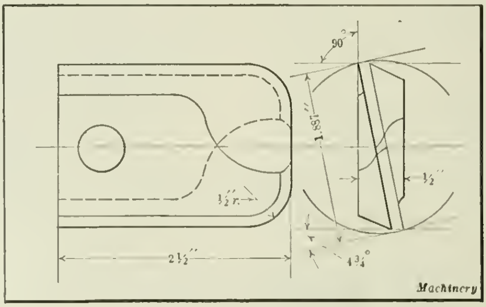

Fig. 2. Special Reamer Blade

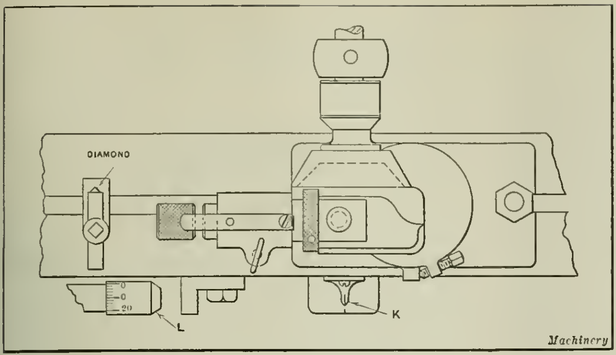

Fig. 3. Plan View of Reamer-grinding Fixture shown in Fig. 1

plane at an angle to that of the wheel-spindle. The best results are obtained with the wheel in the lowered position.

It should be noticed that the exact center of the radius of the cutter and the swivel or pivot center both lie in the same vertical line. By registering the graduation of the handwheel when truing the wheel, and carefully setting the machine to this graduation when finish-grinding, the diameter of the reamer can be held to close limits. When the fixture is in operation, the table is first brought forward so as to take a light trial cut, beginning at the rear end of the reamer and working the table to the left until the pointer lines up with the radius center line of the stationary plate. The table feed is then stopped and the arm carrying the cutter swung through an angle of 90 degrees to form the half-inch radius. The table is again moved to the left until the center stop *L* is reached. The movement of the table is then reversed and brought back to its original position where the cutter is indexed around 180 degrees, or one-half turn. The grinding operations are then repeated.

Hand feed and hand pressure on the arbor, while in both positions, are necessary, as mechanical feeds cannot be used. After finish-grinding, the rear of the side edges are stoned off slightly tapering, the clearance being worked into a negative one. This stoning prevents the rear of the blade from scraping the side of the cavity if slightly out of alignment. The reamer, when ground and stoned as described, produces a very smooth finish, and in the case of high-explosive shells gave the finish required to pass the rigid government inspection. Those familiar with the manufacture of high-explosive shells know that the cavities must be perfectly smooth, as any rough spots would cause friction with the explosive which is set in a rotary motion only by its frictional contact with the walls of the cavity. In order to prevent dangerous premature explosions, it is therefore necessary that exceptional care be used in the manufacture and inspection of munitions of this type.

TORCH FOR CUTTING METAL UNDER WATER

A new type of metal-cutting torch designed for operation under water has recently been tried out at the shipbuilding works of the Chantiers du Rhone at Lyons, France. Demonstrations conducted by Eugene Royer, assisted by an American naval attaché and a former representative of the United States Shipping Board, showed that a clean cut can be rapidly made while the metal is submerged. Experiments were made on a piece of armor plate about 11/16 inch thick and 6 11/16 inches long which was entirely submerged in a basin of water. When the blowpipe or torch was plunged into the water the latter immediately began to bubble. The metal finally became severed under the action of the torch, which is said to attain a temperature of about 6500 degrees F. In one minute forty seconds the 11/16-inch steel plate was completely cut through its entire length of 6 11/16 inches.

The lighting of the torch is automatic, and the torch can be readily adjusted to the proper distance from the work. It is claimed that the development of this apparatus will make possible the repairing of ship hulls under water, so that the ships will not have to be put in drydock or careened, and that wrecks or obstructions in shipping channels can be cut up so that they may be readily removed.

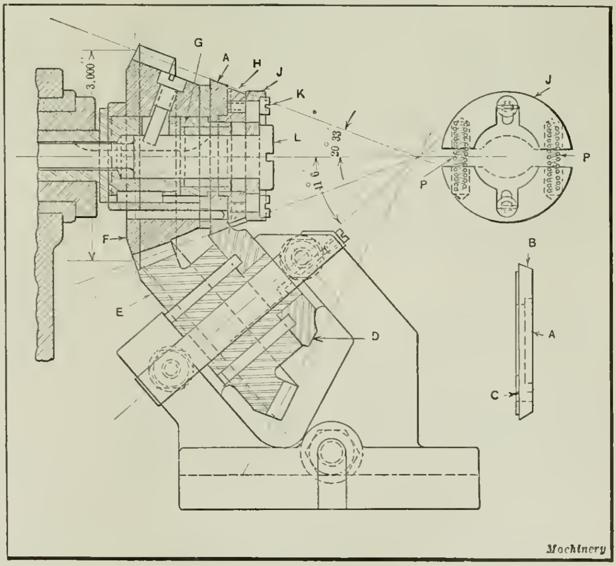
Paris, France W. P. MITCHELL

KNURLING FIXTURE

A large quantity of aluminum castings like the one shown at *A* were required to be knurled on unequally spaced portions of the smoothly finished beveled edge *B*. The knurled portions were to be located in a given position relative to a hole *C*. To meet these requirements, a fixture such as shown in the illustration was made. The knurling tool *D* and the work *A* are mounted on bevel gears *E* and *F*, respectively. This prevents slippage between the work and the knurling tool and enables the knurled surfaces on the tool to be accurately reproduced on the work. Sufficient allowance was made in cutting the bevel gears to provide for feeding the tool in 0.01 inch, which was the depth of knurl required.

The work is held on arbor *G* by a spring washer consisting of members *H*, *J*, and *K*. When the clamp bolt *L* is released, the halves of member *J* are separated sufficiently to pass over the head of bolt *L*, by means of springs *P* shown in the view to the right.

Waynesboro, Pa. D. A. NEVIN

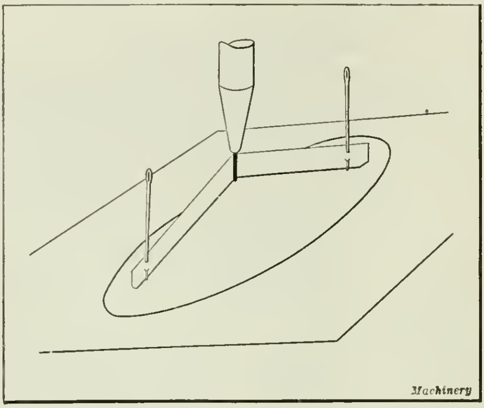


Fixture for performing a Special Knurling Operation on Work A

METHOD OF DRAWING AN ELLIPSE

When it is necessary to draw ellipses quickly, the writer employs a modification of the well-known "string-and-pin" method. With the modified or improved method, the string is replaced by a strip of vellum or bond tracing paper 5/16 inch wide. Two sewing needles are used for pivots, as the needles have finer points and a smoother finish than ordinary pins. Two crosswise pencil marks are made on the paper strip a distance apart equal to the length of the large main diameter of the desired ellipse plus 1/16 inch. The strip of paper is then pierced by the needles on these lines in a "weaving" manner, as shown in the illustration. The ends of the paper strip should extend 1/4 inch beyond the needles.

A thin lead held in a pencil-holder is used for drawing the curve. The lead should protrude a little over 5/16 inch from the holder. By holding the pencil vertical and keeping the paper strip stretched at an even tension, the resulting ellipse will be fairly accurate and even. The paper strip is sufficiently wide to assist in supporting the pencil perpendicular to the paper. As the end of the pencil-holder is wider than the lead, it prevents the paper strip from slipping up



Quick Method of drawing an Ellipse

on the lead. One strip of paper is usually suitable for drawing at least half a dozen ellipses before it wears out.

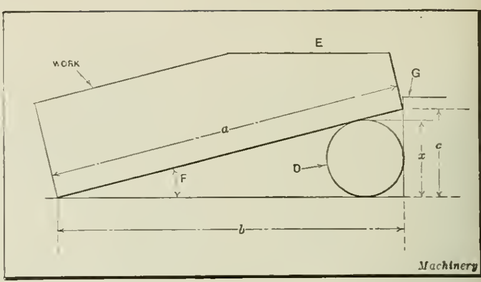
By locating the needles in the drawing-board at varying distances it is possible to produce ellipses of varying small diameters that always have the same large diameter, or in other words, ellipses that are projections of the same circle at varying angles. The pencil lines may be inked in by the use of celluloid curves or a compass. It is necessary to add 1/16 inch to the large diameter when marking off the lines on the paper strip, to compensate for the thickness of the lead. Permanent templets may be produced from thin sheet celluloid by first tracing the ellipse with a steel point in place of the lead, and then carefully cutting the celluloid on the traced outline.

Detroit, Mich. A. L. Vargha

SETTING WORK AT AN ANGLE BY USE OF DRILL ROD

The writer has found that drill rod provides a simple means of setting up work at an angle for testing or grinding. The accompanying illustration shows graphically the method of using the drill rod. It is, of course, necessary that the opposite sides of the work be straight and parallel, as otherwise some deviation from the proper angle will result.

Referring to the diagram, E represents the surface of the work to be ground. The lower edge rests on the magnetic chuck, and the other end is supported by the drill rod or



Method of setting Work at an Angle by Use of Drill Rod

plug D. Both the work and the drill rod are in contact with the straight edge of the chuck, or a ground parallel G.

The following is a simple rule for finding the proper diameter of drill rod to use: Having the angle F given, multiply the dimension a by the cosine of the angle to determine dimension b, and multiply a by the sine of the angle to determine c. Deduct b from a and then deduct the remainder from c. The result is x which is the diameter of the drill rod or plug D. Written as a formula,

$$x = c - (a - b)$$

As an example showing the application of the formula, let $F = 5$ degrees, and $a = 2$ inches; then

$$b = a \times \cos 5 \text{ degrees} = 1.992$$

and

$$c = a \times \sin 5 \text{ degrees} = 0.174 \text{ inch}$$

Then

$$a - b = 2 - 1.992 = 0.008$$

and

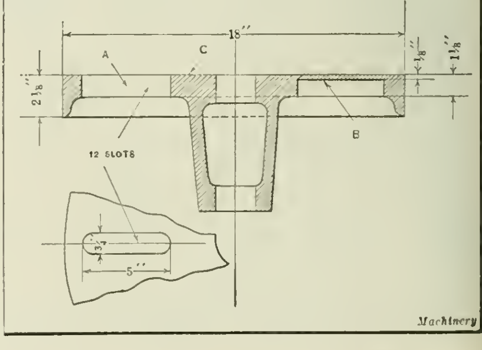
$$x = 0.174 - 0.008 = 0.166 \text{ inch}$$

Bridgeport, Conn. Walter W. Wright

REDESIGNING SLOTTED CASTING TO FACILITATE MACHINING

The machining of a casting similar in appearance to a slotted faceplate was greatly facilitated by a simple change in the casting as indicated at B in the accompanying illustration. This casting was used on a special machine and was required to be face-turned on the surface C. Ordinarily castings of this kind would be made with the slots extending clear through the flange as indicated at A.

To insure a clean turned face without the edges of the slotted holes being broken or ragged, the foreman ordered the castings made with a filler 1/8 inch thick at the top face of the holes, as indicated at B. This permitted the first, or roughing, cut to be continuous. The fine finishing cut, which followed the roughing operation, was of just sufficient depth to cut through the 1/8-inch filler section, leaving the face of the plate and the edges of the slotted holes clean and smooth.



Casting which was redesigned to facilitate Machining

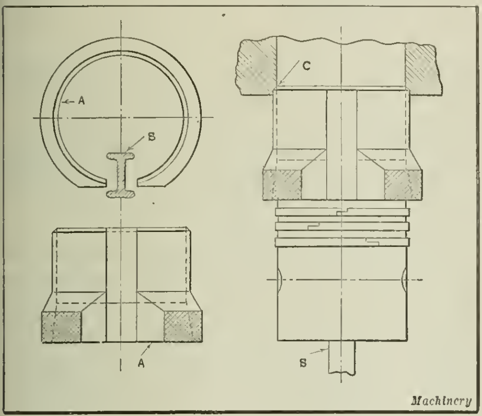
The castings were made in green sand, but better castings could, of course, be made if dry sand cores were used to produce the slot recesses. The stock *B* at the top of the slots should not be less then ⅛ inch in thickness.

Kenosha, Wis. M. E. Duggan

DEVICE FOR ASSEMBLING PISTONS IN CYLINDERS

The ring shown at *A* was developed to facilitate inserting assembled pistons into the cylinder bores of automobile engines. The ring is in the form of a sleeve with a tapered hole in one end which enables the piston-rings to be compressed or forced into position in the piston-grooves before entering the cylinder bore. It will be noted that the ring is split or slotted on one side to allow it to be slipped off the connecting-rod *B* after the piston is in place.

The ring is made heavy at one end to insure sufficient strength at the point where the rings are compressed, while the end which slips into the countersunk bore of the cylinder at *C* is only about 1/16 inch thick. The outside of the large end is knurled to enable the ring to be handled easily, even when covered with oil.



Device used in assembling Pistons in Cylinders

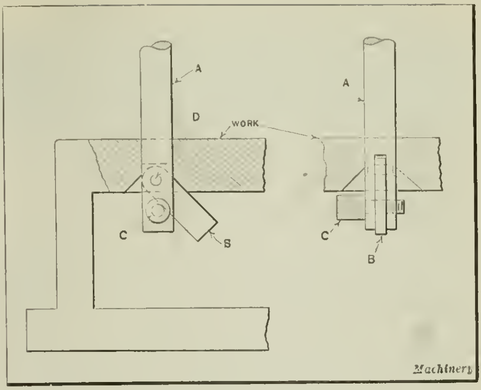
This device is inexpensive, and saves time and unnecessary labor, because all the mechanic has to do is slip the ring over the piston, insert it in the countersink at the bottom of the cylinder in the position indicated in the view at the right, and then push the piston up into position.

Pittsburg, Pa. William Owen

COUNTERSINKING TOOL

It is sometimes necessary or desirable to countersink the inner end of a hole which has been drilled through a cast-iron shell or through work such as that shown in the accompanying illustration. Countersinking operations of this kind can be easily performed by the use of a tool like the one shown in the illustration. This tool consists of a shank *A* made from drill-rod stock, a tool-steel cutter *B*, and a knurled-head screw *C*. The shank of the tool is held in the drilling machine spindle. From the illustration it will be noted that the drill-rod shank is slotted to accommodate the cutter *B* which swivels on a pin *D*.

The cutter is held in the correct angular position for countersinking holes by the knurled-head screw *C*. Screw *C* also serves to prevent the slot in which the cutter is held from spreading when the cut is being taken. When the knurled-head screw is removed, the cutter *B* folds down into the slotted end of shank *A*, thus permitting the tool to be inserted in the hole which is to be countersunk. When the end of the tool projects a sufficient distance from the



Tool for countersinking Inaccessible Holes

inner end of the hole to permit the cutter to be pivoted into the correct cutting position, as shown in the illustration, screw *C* is inserted after which the countersinking operation can be performed by feeding the tool upward. After the hole is countersunk to the required depth, screw *C* is removed to permit the tool to be withdrawn from the hole.

Rosemount, Montreal, Canada Harry Moore

SUPPORTING SHOULDERED WORK ON V-BLOCKS

It is sometimes desirable to place V-blocks under a shaft having two or more shoulders, or sections of different diameters. In order to keep the center line of the work parallel with the surface plate, a parallel pad or series of shims and pads must be put under the V-blocks which are used to support the smaller sections. In the accompanying illustration the pad *P* is employed to bring one of the V-blocks up to the correct height for supporting the section having the smaller diameter. The method of determining the correct height *H* of pad *P* is as follows:

Let a = angle of V-block;
R = radius of large part of work; and
r = radius of small end of work.

With these values known, it is desired to find the height *H* of pad *P*.

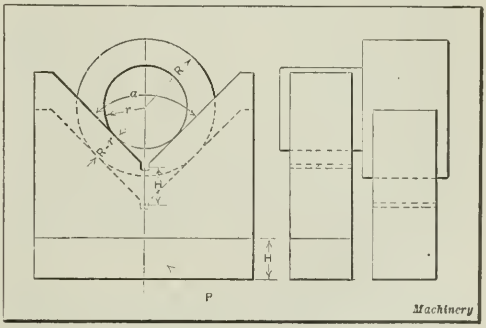
By trigonometry

$$H = (R - r) \text{ cosec } \frac{a}{2}$$

Therefore, when the angle a of the V-block is 90 degrees we have

$$H = 1.4142\ (R - r)$$

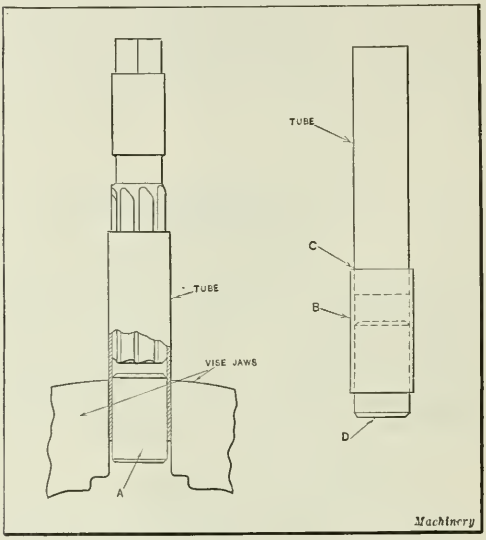
Flint, Mich. W. G. Holmes



Method of using V-blocks to support Shouldered Work

HAND-REAMING THIN TUBING

In making small pump cylinders or other apparatus from thin brass tubing, it is often necessary to ream out the tubing to size with a hand reamer. In performing the reaming operation, difficulty is sometimes encountered in holding the tubing without distorting, cutting, or crushing it. If only a small amount of metal is to be removed, one end of the tube may be gripped by a fine-tooth Stillson wrench, but there is always danger of damaging the work when this method is used. The best way is to drive a brass or iron plug *A* into one end of the tube as shown in the illustration, and then grip this end in the vise, preferably with a V-block between one jaw and the tube. The reamer may then be run in without difficulty. If the tube to be reamed is short, it can be driven into a larger one, as shown in the right-hand view. In some cases the sleeve *B* is split and spread out, after which it is soldered into place at the joint *C*. A plug *D* can then be driven into the extension sleeve *B* and gripped in the vise as shown in the view previously referred to. The extension sleeve should be long enough to



Method of holding Tubing while reaming

allow the reamer to run through the upper tube before bottoming on the plug. After reaming, the sleeve may be released by heating it so as to melt the solder.

Oakland, Cal. H. H. Parker

REGRINDING THE TEETH IN METAL-SLITTING SAWS

It is not always cheaper to regrind the teeth in metal-slitting saws than it is to buy new saws. There are times, however, when regrinding a saw that is practically worn out may be profitable. It may happen that there is a particular job to be rushed through which requires a certain size saw, and the saw available for this job may be dull or of no further use in its present state. If the time required to obtain a new saw would delay the job considerably, the regrinding method described in this article can often be used to advantage. It may be mentioned that the method was devised by the writer when a circumstance of this nature arose. By referring to Fig. 1, the idea of the arrangement will be readily grasped.

The block *A* on which the saw rests was one of the attachments supplied with the grinding machine. Across the top face of this block there is a groove and on the opposite

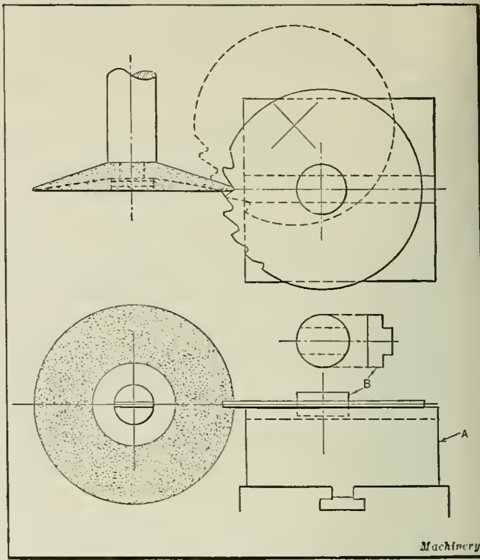


Fig. 1. Method of grinding Metal-slitting Saws

face a tongue. A small stud *B* with a tongue or key across one end, of the proper width to fit the groove in block *A*, is the only part that was required to be made in this particular instance. The saw fits and rotates about stud *B* as a center, and the key permits the saw to be drawn back and forth, to and from the grinding wheel.

The grinding wheel should be of a coarse grade and fairly hard, as the nature of the work tends to wear the wheel away rapidly. The teeth are first notched, the eye being relied upon to determine the proper depth. If the cutting edge is to be radial, a scale or straightedge placed across the grinding wheel will enable the center piece to be properly located. If the teeth are to be under-cut, the table or block can be adjusted to give the angle of under-cut desired.

In grinding the backs of the teeth, the table and block are adjusted to permit the cutter to take the position shown by the dotted lines in the upper view. The angles and general dimensions of the teeth on the most commonly used saws are shown in Fig. 2. Nearly all saws are ground with back clearance, as indicated, and after repeated regrinding the cutter will become slightly under size. By using paper shims the saw can be made to run out of true a sufficient amount to produce the correct width of slot.

HOW AND WHY

QUESTIONS ON PRACTICAL SUBJECTS OF GENERAL INTEREST

TOOLMAKER'S PROBLEM

R. T.—Please show how to find dimension *W*, Fig. 1.

A.—First lay out the diagram shown in Fig. 2 from the dimensions given in Fig. 1. Referring to this diagram we have $b = 2$ inches; $a = 3.375$ inches; angle $D = 20$ degrees; and angle $A = 180$ degrees minus 20 degrees = 160 deg. Referring to MACHINERY'S HANDBOOK, page 152, we find that

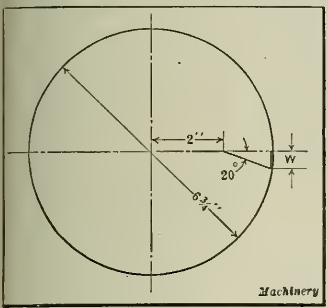

Fig. 1. Toolmaker's Problem

$$\sin B = \frac{b \times \sin A}{a}$$

$$C = 180 \text{ degrees} - (A + B)$$

Then

$$W = a \times \sin C$$

Substituting the numerical values in these formulas, we have

$$\sin B = \frac{2 \times 0.34202}{3.375} = 0.20268$$

and

$$B = 11 \text{ degrees } 41 \text{ minutes } 37 \text{ seconds}$$

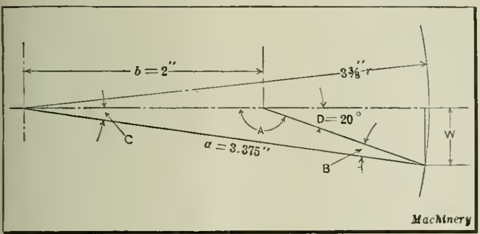

Fig. 2. Diagram used in finding W, Fig. 1

$$C = 180 \text{ deg.} - (160 \text{ deg.} + 11 \text{ deg. } 41 \text{ min. } 37 \text{ sec.})$$

$$C = 8 \text{ deg. } 18 \text{ min. } 23 \text{ sec.}$$

Then

$$W = 3.375 \times 0.14447 = 0.48759 \text{ inch.}$$

ELASTIC LIMIT AND YIELD POINT

H. C. A.—What is the difference, if any, between the elastic limit of steel and its yield point?

A.—The following definitions of the physical properties of materials have been established for use in the testing materials laboratories of the Bureau of Standards:

Elastic limit is the stress which produces a permanent elongation 0.001 per cent of a gage length, as shown by an instrument capable of this degree of precision. This is determined from set readings with an extensometer.

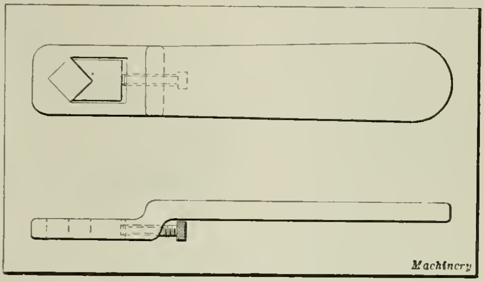
Yield point is the stress at which marked increase in deformation of the specimen occurs without increase in load. This is determined usually by a drop of the testing machine beam or with dividers.

Proportional limit is the stress at which deformations cease to be proportional to the load. This value is determined with an extensometer.

FINISHING WRENCH FORGINGS

S. E.—The writer is having difficulty in attaching abrasive grain to felt polishing wheels for finishing box wrenches, such as shown in the illustration. Patternmakers' glue is used in coating the wheel; this is allowed to dry for a short time and is then stoned down. A second coating is next applied hot, and the wheel immediately rolled in emery. With this method trouble has been experienced from the emery peeling off almost immediately when the wheel is used. The wrenches are made from steel forgings, and are first roughed on a solid emery wheel. Can you give me any information that will assist in overcoming the trouble?

A.—In answering this question it is necessary to know the degree of finish desired. If an ordinary grade of finish is required, after the forgings have been roughed on the solid wheel, use No. 120 alundum for dry-fining. If a better finish than this is required, a second wheel set up with



Adjustable Box Wrench which is finished by polishing

No. 150 alundum may be used. The second wheel should be used with grease in cake form, made from beeswax and suet.

A felt wheel is hardly suitable for a job of this kind; better results will be obtained with a solid bullneck leather wheel. The utmost care is necessary in selecting and preparing the glue. A good grade of blended hide stock glue is recommended. Preheat the wheels so that the hot glue will not become suddenly chilled in setting up the wheel. After the wheels have been rolled in the abrasive, let them dry thoroughly so that the head will become set. This does not mean until they are cold and appear hard, but they should be permitted to set for forty-eight hours before using, in a normal temperature of about 70 degrees F. Drafts near the glue-pot chill the glue and lower its holding efficiency.

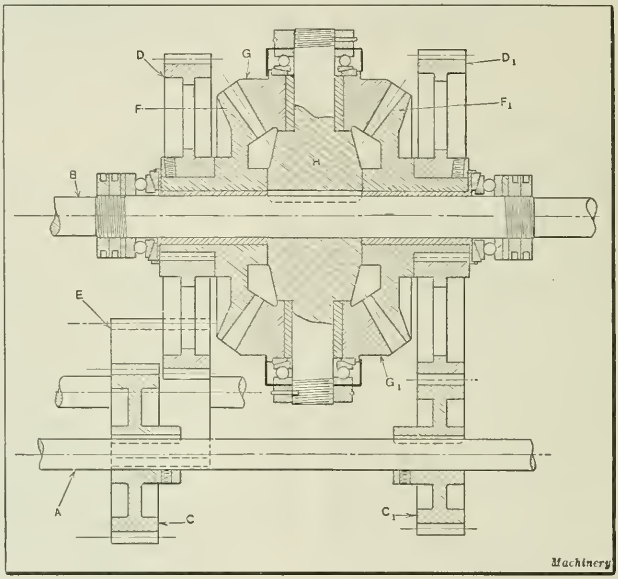
For the highest efficiency in handling a job of the kind mentioned, it is probable that the use of a "compress" polishing wheel made of canvas or leather with a medium density cushion is best. This type of wheel is more expensive than the disk type or the leather-covered wheel, and if such wheels are used, complete instructions as to their preparation can be obtained from the manufacturers of the wheel. With this type of wheel, the wrenches could be finished from the rough without the use of a solid grinding wheel; that is, the wrenches would first be ground with a No. 80 alundum flexible wheel, followed by dry-fining with No. 120, and finishing with No. 150. This will give a high degree of finish, and may be modified somewhat for the ordinary finish, in which case the flexible grinding would be performed with No. 60 alundum and the finishing with No. 120, these two being sufficient. A wheel of medium density cushion would be suitable for covering the entire surfaces of this wrench, if it were not desired to retain the sharp edges of the forging.

SPEED REDUCTION BY DIFFERENTIAL GEARING

By FRANK C. PENNY

A problem that cannot always be easily solved by the machine designer is that of obtaining a speed reduction of large magnitude. Belting may not be suitable, either because it does not give a positive drive from the driving to the driven shaft, or because there is not sufficient room for the pulleys. Lack of room may also prevent the use of chains and sprockets. Spur gear trains often require too many gears, thus introducing high costs and an undue amount of power loss through friction. Worm-gearing is also often objectionable on account of friction losses and the attendant heating. In order to overcome these difficulties, the writer developed, at the plant of the Bridgeport Safety Emery Wheel Co., Bridgeport, Conn., a method of employing differential gearing as a means of obtaining a satisfactory speed reduction mechanism of compact form.

The principle can, of course, be applied in a number of forms and modifications. The form shown in the accompanying illustration is a simple one. The speed reduction is made from the shaft A to the shaft B. As may be seen, the gears C and C_1 are fixed on shaft A. Gear E is merely an idler meshing with gears C and D. Gear D is fixed on the hub of bevel gear F, which is bushed and free to revolve on the shaft B. Gear C_1 meshes directly with gear D_1. Gear D_1 is mounted on the hub of the bevel gear F_1 which is bushed and free to revolve on shaft B, the same as gear F. The crank H is keyed to the shaft B, and on its two arms are mounted the bevel idler gears G and G_1 which are bushed and free to revolve on the arms.



Speed Reduction Mechanism employing Differential Gearing

Now as C and C_1 are keyed to the shaft A, it is evident that they must always turn or rotate in the same direction. It should be noted further that C_1 drives direct to D_1 and that C drives D through the idler gear E. Therefore D and D_1 must revolve in opposite directions. Their speeds are also different, as gear C has more teeth than gear C_1. Gears F and F_1 must, of course, revolve with gears D and D_1 which are mounted on their respective hubs. The bevel gears G and G_1 meshing with both F and F_1 must therefore revolve on their own axes. If F and F_1 should revolve at the same speed but in opposite directions, gears G and G_1 would be stationary with respect to the axis of the shaft B, that is, they would revolve on their own axes, but they would not revolve about shaft B. Now if F and F_1 should revolve at different speeds, G and G_1 must revolve about the axis of the shaft B, and thus revolve shaft B through crank H.

Determining Amount of Speed Reduction

The calculations entering into the design of a speed reduction device of this kind are simple. As in laying out gear trains of any type, it is largely a matter of employing cut-and-try methods. The number of revolutions per minute of shaft B, which is driven by crank H will be one-half the algebraic sum of the number of revolutions per minute of the speeds of the bevel gears F and F_1. In order to make this clear, let it be assumed that a point on the pitch circle of gear F_1 is traveling at a rate of $x + y$ feet per minute, and that gear F is stationary. It is obvious that a point the same distance from the center of shaft B on the axis of G and G_1 will travel at a speed of $\frac{1}{2}$ $(x + y)$ feet per minute.

Now assume that a corresponding point on gear F is traveling at a rate of x feet per minute in the opposite direction or $-x$ feet per minute, and consider gear F_1 to be stationary. The corresponding point on the axis of gears G and G_1 will now travel at a rate of $\frac{1}{2}$ $(-x)$ feet per minute. Next assume that both gears F_1 and F are traveling at their respective speeds of plus $x + y$ and minus x feet per minute. Now adding the speeds of F_1 and F we obtained $x + y - x = y$ feet per minute. Then a speed of one-half y feet per minute equals the speed of the point under consideration on the axis of gears G and G_1.

Now as the pitch diameters of gears F and F_1 are equal and cannot be otherwise, and as these gears mesh with gears G and G_1, it is evident that the number of revolutions per minute can be readily employed to designate the speed. Therefore, the speed of shaft B can be expressed as one-half the algebraic sum of the revolutions per minute of gears F and F_1. The selection of the bevel gears is merely a matter of choosing such sizes as can be used in the available space, and still be of sufficient size to give the necessary tooth strength for the material used and the load imposed. The diameters of gears G and G_1 should, of course, be made as large as permissible so that they will not revolve on the crank H at a higher speed than necessary. In determining the sizes of the spur gears to be used, it is only necessary (not considering the available space) to select such sizes as will give the desired difference in speed between F and F_1, together with a suitable surface speed.

The following example will serve to make clear the procedure followed in laying out or designing a speed reduction device of the type shown in the illustration. We have shaft A running at a speed of $-$ 625 revolutions per minute (anti-clockwise), and it is desired to drive shaft B from shaft A so that shaft B will revolve in a clockwise direction at a speed of approximately 3 revolutions per minute. The algebraic sum of the speeds of gears F and F_1 must, therefore, be about $+$ 6 revolutions per minute. Taking 300 revolutions per minute as an approximate speed for F_1, we may proceed to determine the pitch and size of the gears to be used.

Let it be assumed that we select an 8-pitch gear having a pitch diameter of $7\frac{1}{2}$ inches for D_1 and an 8-pitch gear having a pitch diameter of $3\frac{1}{2}$ inches for gear C_1. These gears will give bevel gear F_1 a speed of $+$ 291.67 revolutions per minute. The speed of gear F should therefore equal approximately — 291.67 + 6 or — 285.67 revolutions per minute. Now if gear D has a pitch diameter of 7 3/8 inches and gear C has a pitch diameter of 3 3/8 inches, gear F will have a speed of approximately — 286.02 revolutions per minute. The difference between the number of revolutions of gears F and F_1 will then equal 5.65 revolutions per minute, and the speed of shaft B will be one-half as great or + 2.82 revolutions per minute.

It is, of course, difficult to obtain an exact speed for shaft B, but by using gears of as fine a pitch as possible without an undue sacrifice of strength, we can obtain very nearly the exact speed desired. The center distance between the two shafts can in some cases be varied, thus increasing the range in speed reduction that may be obtained.

The possibilities of a speed reduction device of this kind is readily apparent to the designer. The speed of the shaft B with respect to shaft A is governed entirely by the speed

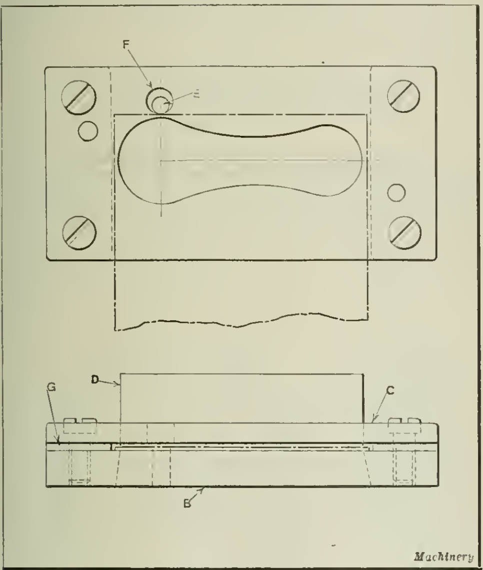


Fig. 1. Temporary Blanking Die

ratio existing between the gears D and D_1. The speed of shaft A may be as high as the successful operation of the gears will allow, and still by the right combination of gears it may be possible to obtain a very low speed for shaft B. At the same time the whole gear assembly is very compact, and may be installed where other forms of speed reduction mechanisms cannot be used. In order to obtain the best results, all the running parts should, of course, be well oiled and this may be readily accomplished by running the whole assembly in an oil bath or in a case partly filled with oil. Operated under these conditions, the friction loss is very low.

* * *

With the general recovery of trade, South American exchanges may be expected to rise. The Argentine Republic will unquestionably return to gold exchange within a comparatively short time. The fall of exchange usually caused by excessive buying and insufficient selling carries within itself its own remedy. By cutting down the country's buying power it reduces imports and lowers prevailing wages by comparison with outside standards, which should in time foster exports. The reason for the activity of the copper mines in Chile while the mines in the United States were idle, was the low cost of Chilean labor in gold.—Paper by Mr. De St. Phalle, read before the Foreign Trade Convention.

BLANKING AND PERFORATING DIES FOR EXPERIMENTAL PURPOSES

By D. A. NEVIN

The use of so-called "temporary" dies has effected a great saving in many instances in the cost of producing sheet-metal parts. The discarding of expensive blanking and perforating dies during the process of developing and perfecting a new model is unnecessary when temporary dies are used, as dies of the latter type can be employed until the stamp of approval has been placed on the product by the purchasers. The expense of making alterations in the product during its period of development is generally less if separate dies are used for the blanking and perforating operations, as was done in the case of the temporary dies described in this article. This practice allows alteration of the shape of the part without affecting the punch and die for perforating, and the

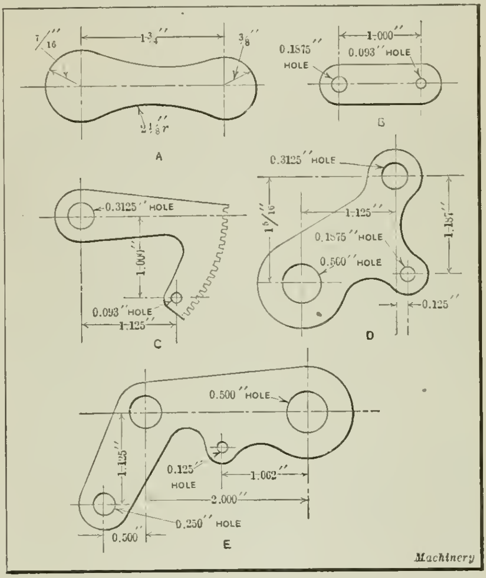

Fig. 2. Parts produced on Temporary Dies

perforating die can be altered without affecting the design of the blanking die.

Construction of Blanking Die

The blanking die shown in Fig. 1 is used for blanking the piece shown at A, Fig. 2. This piece is made from 0.050 inch flat steel. Referring to Fig. 1, the die proper B is made from 0.3125-inch tool steel, and the stripper plate C is made somewhat thicker than is the usual practice (0.1875 inch in this case) for the purpose of guiding the punch D, which is ground flat on its top surface. A plain stock stop-pin E is shown just under the sight-hole at F. The spacer guides G allow sufficient clearance to permit the stock to be raised up over the stop-pin when feeding the stock to the next position. By this method of construction a self-contained punch and die is obtained, thus saving the expense of the sub-press design, as well as the cost involved in assembling the punch and die.

It is also an improvement over the old-style of temporary punch and die which did not have the punches guided in the stripper plate and which required the punch to be fastened to the ram and the die to the bolster after alignment of the members. The tool here described, produced very satisfactory work and stood up well during the production of more than 50,000 parts. If properly made and if the requirements

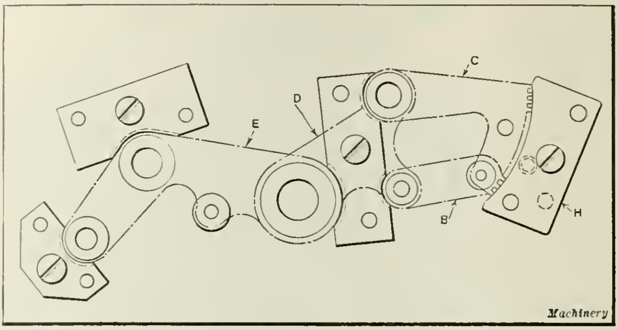

Fig. 3. Perforating Dies of Temporary Type

of production justify the expense, a die of this type can be mounted on a standard sub-press.

Construction of Combination Perforating Dies

Considerable saving in the cost of constructing perforating dies can be obtained by grouping the parts in suitable combinations, provided a large production is not required. In Fig. 2 pieces *B*, *C*, *D*, and *E* are flat parts such as are used in cash registers, adding machines, typewriters, etc. These parts are blanked out in a die similar to that shown in Fig. 1 and are perforated in a separate operation in the combination die shown in Fig. 3, the locating nests being removed or replaced to suit the part being perforated.

In designing a die of this kind a careful study of the parts to be perforated is made, and the parts are grouped or located on the die in such a way that holes of the same size on different parts can be perforated with the same punch. The nest plates for the die shown in Fig. 3 were designed, as far as practicable, to accommodate more than one piece. In laying out this die, the 0.3125-inch holes of parts *C* and *D*, Fig. 2, were matched so that the same punch could be used to perforate both parts. A study of the other parts and the relative sizes of holes showed that the 0.093-inch hole in part *B* checked with the smaller hole in part *C* and that part *B* also required the punching of a hole 0.1875 inch in diameter which was the same size as the smaller hole in part *D*, so that in locating the latter part it was swung around the center of the 0.3125-inch hole until the 0.1875-inch hole was placed 1 inch from the 0.093-inch hole in part *C*, thus providing for perforating both holes in part *B* without adding any more punches.

The remaining part *E* has only a 0.500-inch hole which is common to any of the other parts. This part is located with the 0.500-inch hole matched with the same size hole in part *D*. The number of parts that the punch and die is designed to perforate depends on the production required and the number of parts that can be accommodated without the overlapping of holes in the die-plate. The locating nests should be shown on an assembly of all the nests in order to prevent the screw and dowel holes from overlapping. The die-plate is not hardened, the perforating bushings being a light press fit therein, allowing for their ready removal.

Part *C* or *E*, Fig. 3, may be perforated without removing any of the nests. For perforating part *B*, the nest *H* is removed and exchanged for the nest *J* shown in Fig. 4. In Fig. 4 are also shown the nests *K* for locating part *D*. The perforating punch was mounted in a large sized sub-press in order to allow space for additional parts.

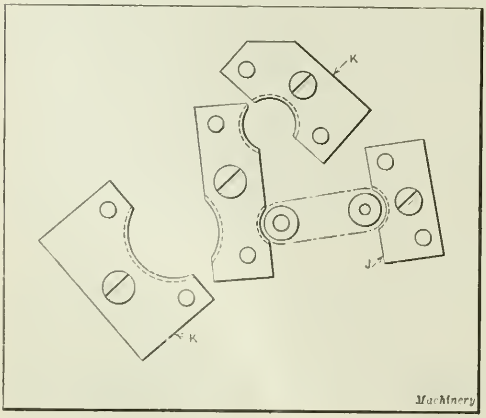

Fig. 4. Diagram showing Method of attaching Locating Nests

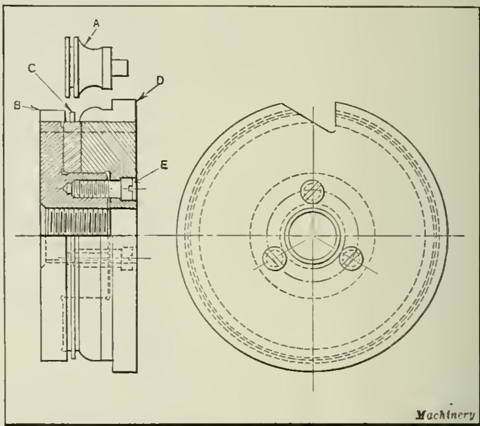
BUILT-UP FORMING TOOL

By EDWARD C. PERRY

A circular forming tool is only as efficient as the weakest point in its outline. When one point fails, the better sections alone cannot produce perfect work. In an ordinary forming tool, the broken point is made serviceable only by grinding



Forming Tool of Built-up Construction

away the entire cutting edge. To overcome this apparent waste, the forming tool here illustrated was designed.

The work to be machined is shown at *A*. The difficult feature is a narrow groove 3/64 inch wide by 3/32 inch deep. The thin projection on the forming tool, which cuts this groove, invariably breaks down before any other part, and frequently requires to be replaced. For this reason, the forming tool is divided into three parts *B*, *C*, and *D* as shown. Part *B* is made with a hub which carries part *C* and fits into part *D*. Part *C* is free to revolve on part *B*, except when held in place by the clamping action of three small screws, one of which is shown at *E*.

When the cutting edge of part *C* has worn out, the screws are loosened and the broken down edge raised above the cutting edge of parts *B* and *D* by revolving *C* about its central bearing. The screws are then tightened and the tool ground. The screws *E* are not depended upon to hold the parts in line while the tool is in use; when it is in the machine, the toolpost screw threads into part *B* and draws the latter toward the post, thus clamping the three parts securely in place.

The British Metal-working Industries

From MACHINERY'S Special Correspondent

London, May 15

DESPITE the serious labor disputes that have hampered industry for some time, it is generally agreed that the long period of depression, though by no means over, is now on the mend. There is a steady expansion in iron and steel production, and this indicates a general improvement.

Effect of Engineering Lock-out in Metal-working Industries

The effect of the continued lock-out is felt in varying degrees in the metal-working industries. With demand much below normal, deliveries have been fairly well maintained, but disorganization is becoming more apparent as a whole. Manufacturers who employ a large proportion of skilled workers have naturally suffered more severely than those engaged on work that is done principally by automatic and semi-automatic machinery.

In the automobile and motorcycle industries, which have considerable orders on hand, output has been reduced by 25 per cent; there is a less marked effect in the machine tool field, as this branch has been greatly depressed for a long time, and the output has been very low. Foremen, apprentices, and machine operators have kept the shops open, and some progress has thus far been made with what few orders were in process when the lock-out started.

Machine Tool Trade

The improved prospects in other spheres of engineering are beginning to make themselves felt in the machine tool field. During the past month and before the full effect of the lock-out was felt, home inquiries for new machine tools were numerous, and for the first time in over a year, a moderate amount of business had been transacted in general engineering tools. In the Clyde district, there have been inquiries for special machines to drill and face pipe flanges, and for heavy vertical drilling and boring machines. Radial drilling and tapping machines are being sold to general engineering firms, and prices are generally very low. There is also some demand for boring and turning mills and ordinary light horizontal drilling, boring, and milling machines. Export trade in machine tools is developing, some inquiries having been received from Australia, South Africa, and India.

British products seem generally to be in greater demand on the Continent, but trade in the Far East which recently has been developing has lately fallen off, although to offset this South America is becoming a more active buyer.

Iron and Steel Industries

It has already been mentioned that the iron and steel trade is showing steady progress in output, and British producers have entirely regained the proportion of the home market that went to the Continent a year or so ago. The demand for alloy steels is strong, principally on account of the needs of the automobile industry. Inquiries are being received from Germany, and fairly large quantities of iron are going to that country; France and Italy have also recently become fairly large customers, and substantial business is expected shortly for reconditioning Indian railways.

A Darlington firm is reported to have secured contracts for the construction of eighteen steel bridges for the Siam State Railways; these railways are also asking for quotations for ten locomotives. The Bulgarian Ministry of Commerce is in the market for machinery, tools, and materials, for the exploitation of the state mines in that country. Canadian buyers seek to place orders in the United Kingdom for 1200 tons of 12-inch cast-iron pipes for spring delivery, and a quantity of electric cranes and other loading and unloading equipment for docks is required.

A contract for 400 locomotives has definitely been placed by Rumania with prominent British builders. Not only is this contract among the largest ever placed in this field of engineering, but there is also talk of further purchases of a similar nature being made.

New Gearing Developments

In the field of gearing, two interesting departures from general practice have been made. One is the Hotchkiss-Taylor gear in which the normal rack form is contained in a plane tangent to a cylinder, the basic gear form of the system being a crown wheel, the teeth of which are involutes in a plane normal to the crown wheel. In this tangent rack system, any gear whether cylindrical or conical, can be meshed with any other gear if it is conjugate to the basic tangent rack crown wheel, and if the base circles or normal pitches are equal. A spiral bevel set with intersecting axes, a double helical bevel set with intersecting axes, and a spur gear set have been made. In each of these sets the larger gear is a crown wheel. Bevel gears with non-intersecting axes, and a worm-gear, the axis of which lies in the tangent plane, can also be produced. Great interest is being displayed in the new system.

Another gear development suggested is even more revolutionary. In this case the pinion of a pair of gears, instead of having teeth, is made with an annular space completely filled with rollers that are long enough to extend across the full face of the pinion. The rollers are held in position radially by lips at each side of the pinion, and the teeth of the gear form their own spaces in the pinion by displacing the rollers as they engage the pinion.

Imports and Exports of Machine Tools

The March returns of imports and exports of machine tools, as compared with the month immediately preceding, show a substantial increase in exports—from 990 to 1447 tons, and from £125,082 to £184,776 in total value; these figures are higher than at any time since last August. The general direction of the curves appears to be changing from downward to upward, and seems to bear out the more optimistic feeling as to increasing trade. The value per ton has risen slightly, from £126 to £128. The imports have risen to a less extent—from 268 to 343 tons and from £35,387 to £37,338 in total value. There is a heavy fall in the value per ton of imports, namely, from £132 to £109. Compared with the first three months' exports of last year, the exports for the same period this year are barely half in value, and little difference is noticeable in value per ton.

Prices and Materials

Metal prices have remained steady during the past month, although one or two items, namely finished iron bars and copper, show a tendency to increase in price. Steel-making irons are in greater demand, and the market for semi-finished material remains satisfactory. The demand for foundry iron is low, but preparations are being made for the blowing-in of more furnaces to meet the increased requirements that are expected.

Billings and Spencer Die Milling Machine

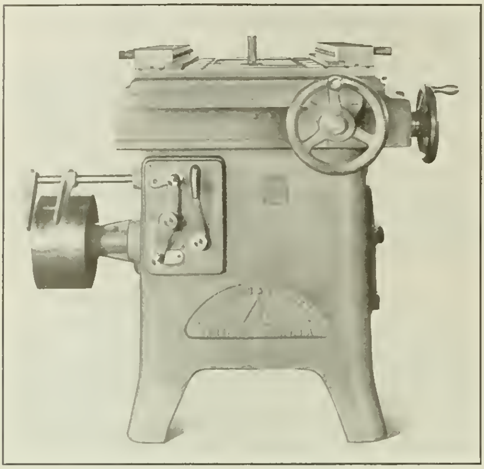


Fig. 1. Machine for milling the Outline of Blanking and Trimming Dies, which has been redesigned by the Billings & Spencer Co.

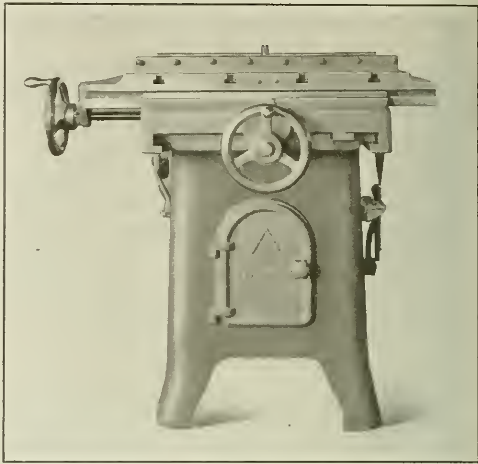

Fig. 2. End View of Die Milling Machine which clearly shows the Construction of the Horizontal and Transverse Slides

MILLING the irregular outlines of blanking dies and dies for trimming the flash from drop-forgings is frequently a troublesome operation on ordinary vertical milling machines because of the difficulty of observing the work clearly while the operation is in progress. For facilitating such work, the Billings & Spencer Co., Hartford, Conn., is introducing a redesigned milling machine which is shown in the accompanying illustrations. All types of cutting dies for presses may be milled on this machine, with or without clearance draft. The outline of the work is in full view of the operator at all times. The main feature of the machine is the inverted spindle at the center, in relation to which the work is shifted horizontally and transversely at the will of the operator.

This adjustment of the work in relation to the spindle is accomplished by means of two slides, on the top one of which the work is clamped by two parallels adequately supplied with clamping screws. Eight slots on the top slide provide for placing these parallels various distances from the center of the machine so that work varying considerably in size can be handled. The arrangement of the top slide may be clearly seen in Fig. 3. Movement of the slides is obtained through screws actuated by handwheels. Both screws have graduated dials which aid in milling work accurately. The most convenient position for the operator is with one handwheel at his right and the other at his left. A proper sliding fit of the two slides is insured by the use of gibs, and both slides have ample bearing surfaces and narrow guides.

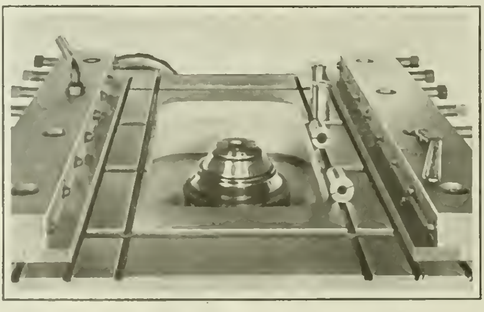

Fig. 3. View looking down on Top Slide and Its Clamping Parallels and the Spindle Nose

Four speed changes for the spindle are readily obtained by shifting the levers of a speed-change box. These levers may be seen in Fig. 1. The gears of the speed-change box are driven direct from the constant-speed pulley. The cutter is held in the spindle by a spring collet, the machine being regularly supplied with collets for holding 3/8-, 1/2-, 5/8-, 3/4-, and 1-inch cutters. The method of holding the cutter in the collet is such as to enable the die to be under-cut to any desired draft. Gripping or releasing of the cutter in the collet in inserting or removing it is effected by operating the upright hand-lever conveniently located on the speed-change-box cover. The spindle is mounted in ball bearings, and all power-driven rotating parts are similarly equipped. Particular care was taken in designing the machine to provide for ample lubrication of the spindle bearings and to insure disposal of chips.

Some of the specifications of the machine are as follows: Size of die that can be accommodated, 3 1/2 to 17 1/2 inches in width and up to any length; travel of longitudinal slide, 12 inches; travel of transverse slide, 4 1/4 inches; speed of cutter, 281, 421, 619, and 926 revolutions per minute; speed of driving pulley, 300 revolutions per minute; floor space occupied, 49 by 58 inches; and weight, approximately 2100 pounds.

* * *

THE AUTOMOBILE INDUSTRY

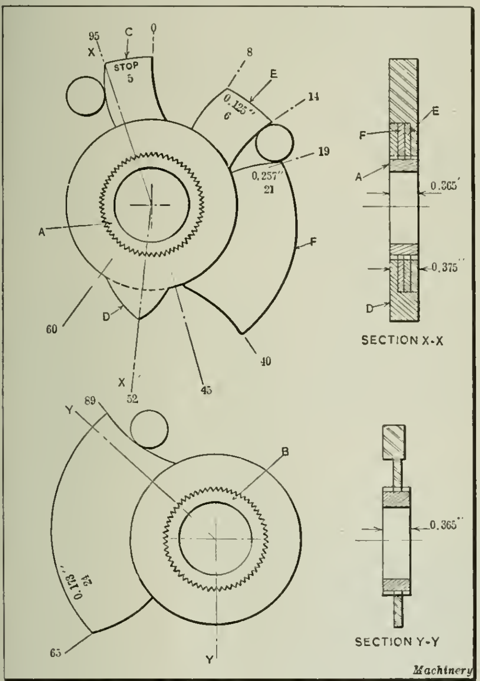
The automobile industry, as a whole, is in a better position today than it has been for the last year and a half. The shops of the leading manufacturers are well occupied, but owing to the readjustment that is taking place in the industry, many of the less well known cars find competition very keen, and it is expected that some of these will not survive. The production of passenger cars during the month of April was about equal to that during March—about 153,000 cars being produced each month. The plans for May called for about the same number of cars.

UNIVERSAL CAMS FOR AUTOMATIC SCREW MACHINES

By D. A. NEVIN, Chief Engineer, Watters Corporation, St. Louis, Mo.

A set of adjustable cams for use on a No. 00 Brown & Sharpe screw machine is shown in the accompanying illustration. These cams are designed to permit the use of various combinations of lobes, and to allow the lobes to be set at different positions on the cam hubs. The lead cam may be made up of four lobes, as shown in the upper view, or it may be made up with one, two, or three lobes, according to the requirements of the work. The nature of the work to be performed must, of course, be considered in selecting the lobes which make up a cam. Lobes that are suitable for drilling and turning operations are made interchangeable with those of the cross-slide cam shown in the lower view.

The hubs *A* and *B* of the lead cam and the cross-slide cam have 90-degree teeth of 1/16 inch pitch cut in their peripheries.



Adjustable Cams for Automatic Screw Machine

The hole in each cam lobe is broached to fit these toothed hubs. The cams are 3/32 inch thick where they come in contact with each other when assembled on a hub, so that the total thickness of four cams is 3/8 inch. The lobes are made of tool steel and are hardened and ground. The cross-sectional view of the lead cam is taken through the stop lobe *C* and the thread lobe *D*. For convenience the amount of throw and the number of hundredths of a complete circle occupied by the cam surface are stamped on the side of each cam lobe. For instance, the notations on lobe *E* show that it has a rise of 0.125 inch and that its cam surface occupies a space equivalent to six hundredths of a complete circle. The thickness of the hub *A* is 0.01 inch less than the combined thickness of the cams, so that the latter are clamped tightly on the camshaft when the clamping nut is tightened. The overlapping sections of the cams are accurately fitted in order to give strength.

The regular locating pin is not used on the No. 00 Brown & Sharpe machine when these cams are employed, as a sufficient grip on the cams is obtained by the clamping nut. If desired, the hub of the cam could be keyed to the camshaft. When combining less than four lobes on the lead cam, washers are used to increase the thickness of the central portion to 3/8 inch. The clamping collars on the camshafts are reduced 1/16 inch in thickness so that the cams will be located centrally. This change does not interfere with the use of the regular cams, which are 1/4 inch thick, as washers can be used to make up the difference in thickness. The cam-roll is made wide enough to allow for the increased thickness of the cams. Only a small variety of thread lobes is required to provide for all threading requirements on the No. 00 machine. The same system may be applied profitably to the No. 0 machine, but on the No. 2 machine the value is not as great.

INDUSTRIAL CONDITIONS IN FRANCE

By MACHINERY'S Special Correspondent

Paris, May 12

While there are no definite indications that any marked improvement will take place in the industrial situation in the immediate future, the results of the international fairs that have recently been held point to some resumption of industrial activity. The Brussels fair had more than 2000 exhibitors from twenty-four different nations. In 1920 only fourteen nations were represented, and in 1921, twenty nations. The business transacted at the fair appears to be as great as in former years. There were definite indications of reductions in machine tool prices. The machine tools exhibited were noted for simplicity in design and for good workmanship. The Paris fair, which is about to open, also promises to be a great success. The number of exhibitors will be larger than last year, and although it is held after the Brussels fair, it is believed that orders of considerable importance will be placed.

The economic situation in France is improving. Over 5,000,000 acres of land were devastated during the war, and of these nearly 4,000,000 acres have been reclaimed. France will probably be able to raise her entire wheat requirements this year, and as the live stock is increasing steadily, food imports will be still further reduced. Production in the coal mines is increasing, 16,000,000 metric tons of coal being exported in 1921. Pig iron and steel were also exported in large quantities. The increase in the value of the franc is doubtless due to these exports, and also to the efforts of the government to balance the budget.

A ruling has been made in regard to the valuation of imports on which tariff duties are paid ad valorem. The percentage of the ad valorem duties varies according to the country of origin of the imports. When a foreign shipment arrives, the wholesale value in the French market is first determined. Then the value on which the duty is applied is figured as equal to the sum which added to the minimum tariff on that sum would make the price of the goods equal to the wholesale price in the French market.

Take, as an example, a shipment of twist drills having a wholesale value in the French market of 10,000 francs. The value on which the duty would be applied would be a figure so determined that after the minimum tariff had been added to it, the sum would be equal to 10,000 francs. The minimum tariff on drills is 20 per cent, and the value placed on them for tariff purposes would be $\frac{10,000 \times 100}{120}$ or 8333 francs.

If the goods came from the United States, the minimum tariff would be applied to this figure, which would be 8333×20 per cent, or 1666 francs. However, if the drills came from Germany, the tariff of 80 per cent would be applied. This would mean a duty of 8333×80 per cent, or 6666 francs.

The importer is required to state the actual value of the goods, and also the sales price in France.

The Machine Tool Industry

FOR the first time in the last eighteen months, it is possible to report a definite improvement in the machine tool industry. There has been—for some months past—a marked improvement in the machine-building industries in general, but the machine tool field has been but slightly affected. Now, however, the records show a rise in the curve of machine tool business above the low level of the past year, and the average of sales of the whole industry has actually increased. While the operation of the shops is far from normal and some are still practically closed, facts clearly denoting improved business should be recorded. Many of the shops entirely closed during part of last year are now operating with small forces. Some of the larger plants that have been operating on extremely conservative schedules have put on increased forces, and others are getting ready to do the same. Some firms that operated at a loss all last year now are able to meet expenses, and some of the leaders in the industry look forward to a steadily improved business from this time on.

Stocks have been reduced in many instances to a point where it is considered advisable to begin building them up again. Compared with 1921, some firms state that their business, so far in 1922, is equal to the entire business of 1921, and in a few instances we are told that the first four months of this year amount to double the business of 1921. The number of firms doing a business more nearly approaching normal is also increasing. At least eight shops are averaging one-half of their capacity business, and, considering the fact that "normal" business in machine tools must be placed considerably below the expanded capacity of the shops, 50 per cent is perhaps not so very far from a normal output.

The activities in the radio field have affected the sale of small automatic screw machines in a marked degree. No automatics of the smaller sizes are available in the second-hand market, and the makers are not able to deliver from stock any longer, but are quoting from four to six weeks deliveries. The sale of small presses has also been favorably influenced by the radio activity.

Prices of machine tools have been reduced in some cases to a point where it is doubtful if even a normal business would make it possible to produce except at a loss, and it is likely that as soon as demand increases, prices in some lines at least will also have to be increased. In this respect the machine tool business will doubtless follow the procedure in the iron and steel business, where prices came down to a low level some months ago, but have since stiffened and have stabilized at a higher level than that to which they first receded. The buying in the machine tool field at present is done almost entirely on price, quality being disregarded in many instances. This condition, too, is likely to change as soon as business in general becomes more active, money is a little easier, and buyers feel they can afford to pay for the best. Nevertheless, even under present conditions, there are buyers who continue to insist upon quality, and are paying for quality in workmanship and materials, which in the long run will prove a wise investment. Some manufacturers have made good use of the time the business depression afforded to so organize their shops and perfect their manufacturing processes that they can maintain high quality without materially increasing the price. But it must not be forgotten that wages in the machine tool industry at present are very nearly double what they were in 1914, and the price of castings still remains practically double that of the pre-war period.

There is a great deal of activity in the development of new machinery. Many new designs have been shown in the mechanical journals during the last few months. Numerous other machines are being designed and developed to be brought out within the next year. These new developments will help stimulate business, as production costs will be brought down by their use. The automobile companies, particularly, are on the lookout for any improvements in the machine tool field, and while very conservative, they have, nevertheless, been among the most active buyers during the last few months. There has also been scattered buying of single machines throughout the entire machine shop field.

LODGE & SHIPLEY AND CARLTON MACHINE TOOL COMPANIES DENY MERGER

In view of the publicity given to a proposed merger in the machine tool field, J. Wallace Carrel, vice-president and general manager of the Lodge & Shipley Machine Tool Co., Cincinnati, Ohio, has authorized the following announcement:

"The Lodge & Shipley Machine Tool Co. is not in any merger or combination. There has been no change in ownership or management. The policy of the company remains the same, and the business will be conducted as it has been in the past."

It has also been announced that the Carlton Machine Tool Co. is not in any merger or combination of machine tool companies and that the ownership and management will remain as in the past.

The Tool Business

The tool shops are better employed at present than they have been for a long time. Most of the tool work comes from the automobile plants. Some die work has also been placed by the radio instrument shops. A growing appreciation of the work of shops specializing in tool design and construction is indicated by the increased buying of tool equipment from such shops by manufacturers who used to do their own tool work.

The demand for accessories in the metal-working field also indicates a general improvement in the business. The sales of abrasive paper and cloth, for example, increased nearly 25 per cent in March over the sales in February, and were almost double the sales of a year ago. The business in grinding wheels is improving, and the sales of wheel-dressers indicate increasing activity in the machine shops. There has been a growing demand for drills, and some of the twist drill manufacturers have increased production. The demand for sheet-metal machinery, including bending and corrugating machines, is good. The electrical tool business is considerably better than the standard machine tool business, and with few exceptions the plants specializing in electrical tools run from 35 to 75 per cent capacity. Some of the old customers have resumed buying, but, on the other hand, it is noted that the orders from the smaller shops have been falling off, doubtless due to financial difficulties. The automobile gear business is booming, and at least one of the shops devoted to the cutting of automobile gears has increased its equipment. The jobbing gear business is improving, but still leaves much to be desired. Were it not for the keen competition and the price-cutting in this field, even the jobbing gear business would show a fair improvement. On the whole, there is now a definite improvement in industry, and while it will be a long time before all adjustments are made to the new conditions, the future is viewed with greater confidence.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW AMERICAN METAL-WORKING MACHINERY

Colburn Heavy-duty Vertical Boring and Turning Mill

ONE of several innovations in the design of vertical boring and turning mills which have been incorporated in a machine now being introduced to the trade by the Colburn Machine Tool Co., 1038 Ivanhoe Road, Cleveland, Ohio, is a patented single-lever control for all feeds and rapid traverses of the tool-heads and rams. Other important patented features include ratchets on the ram saddles which furnish a means of closely positioning the tool-heads relative to the work, spring counterweights for the rams, a reversing mechanism which provides for cutting threads, and a lubricating system which supplies oil to every bearing surface on the machine subject to wear. The machine is built in six sizes which range from 42 to 84 inches swing, inclusive.

The Colburn single-lever control for feeds and rapid traverse of the heads and rams is mounted under each end of the cross-rail, the two head units being separately controlled. The single-lever of the control is moved along cored openings in the cover plate of the control box. This lever is always operated in the direction of the desired movement, whether feed or rapid traverse. When the lever is moved to engage a feed, all traverse gears are automatically disengaged and vice versa.

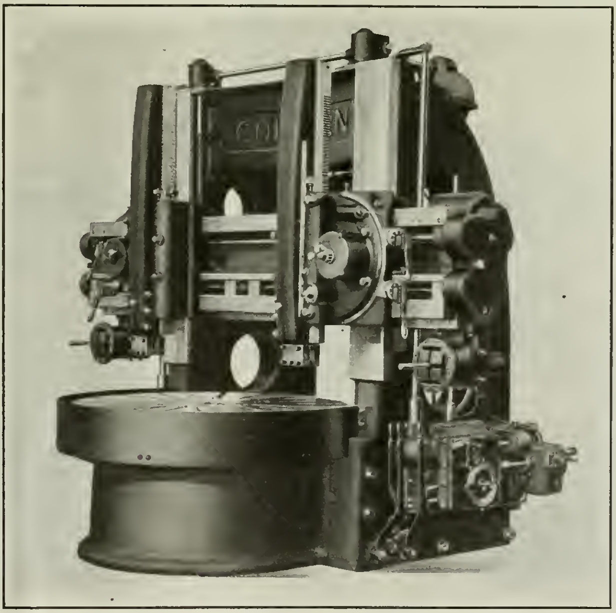

Fig. 1. Heavy-duty Vertical Boring and Turning Mill made by the Colburn Machine Tool Co.

In Fig. 3 the arrows indicate the direction in which the lever is operated to obtain the various feeds and traverse. If it is desired to feed the head at the right-hand end of the cross-rail toward the left, the lever is pushed to the top horizontal slot and then to the left-hand end of this slot. When the head is to be traversed back to the right, the lever is pushed to the extreme right-hand end of the same slot. To obtain vertical movements of the ram, the lever is operated in the vertical slots. In the illustration the lever is shown in the neutral position.

Sixteen feed changes for both horizontal and vertical movements, ranging in geometrical progression from 0.006 to 1 inch per revolution of table, are obtainable through a feed-box on each side of the machine; one feed-box is shown in Fig. 5 with the cover removed. The power rapid traverses allow the heads and rams to be moved at a rate of about 12 feet per minute, and these rapid movements may be secured with the table running or at rest. The rapid traverse mechanism is engaged through the action of a multiple disk clutch in each feed-box.

The cross-rail is raised and lowered by power independently of the table movement through a worm mechanism and gears in oil-tight cases on top of the housing, power being transmitted through a multiple-disk clutch. Raising or lowering of the cross-rail is accomplished by means of a lever on the inside of the right-hand housing. This lever may be seen in Fig. 2, which shows a rear view of the machine. Ball thrust bearings are furnished at the ends of the cross-feed screw and the vertical feed-worms to eliminate wear and reduce the power required to drive the feeding mechanism. The feed-rods and screws are unusually large in diameter.

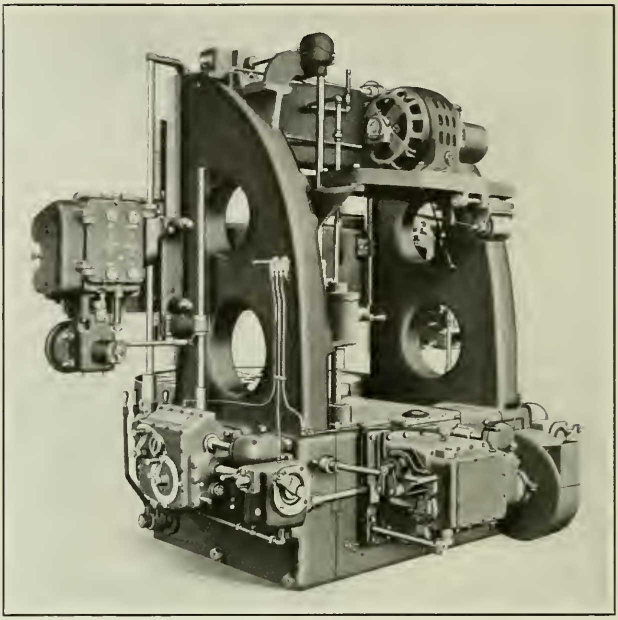

Fig. 2. Rear View of the Colburn Heavy-duty Boring and Turning Mill

The heads are independent in their movements, both as regards direction and rate of feed, and either head may be brought to the center of the cross-rail for boring. The exact central position is determined by a positive hardened stop. Close adjustment of the heads is possible by means of ratchets on the saddles, which have dials graduated to thousandths of an inch. The ratchet, being located on the saddle, is always close to the work, and may be conveniently used while the operator is observing the position of the tool relative to the work. Adjustable taper gibs on the saddles furnish a means of compensating for wear. The rams are also gibbed to the swivel members mounted on the saddles. Bolts are supplied for clamping the swivel members to the saddles when the rams are in the vertical position. A turret head which does not swivel is furnished when desired. This head is always mounted on the right-hand side of the machine and replaces the regular swivel head. The turret has five sides, each of which has tapped holes for attaching box-tools. The turret tilts to an angle of 8 degrees to allow ample clearance for large tools.

The rams have 4 high-carbon steel racks extending their entire length. The rack pinion is made from chrome-nickel steel. The rams may be raised in the swivels sufficiently to allow the bottom of the tool-holders to come flush with the swivels. It is possible to swivel the rams 45 degrees either side of a vertical position, graduations on the swivels indicating the exact setting. The swiveling is accomplished by means of a worm and segment operated through a ratchet lever on the front of each head. The worm and segment of this mechanism also serves as a safety lock to prevent the head from tipping when the clamping bolts are loosened. The rams are counterweighted by a spiral spring enclosed in a steel drum fitted into the front of the heads. This spring can be given any desired tension by operating the ratchet at the front of the drums (see Fig. 1).

Table and Driving Mechanism

The table is a solid casting without cored openings underneath, and has four sets of parallel T-slots planed to accommodate faceplate jaws. Eight radial slots supplement the parallel sets. The table-spindle has a self-centering angular bearing and two vertical bearings which resist all side

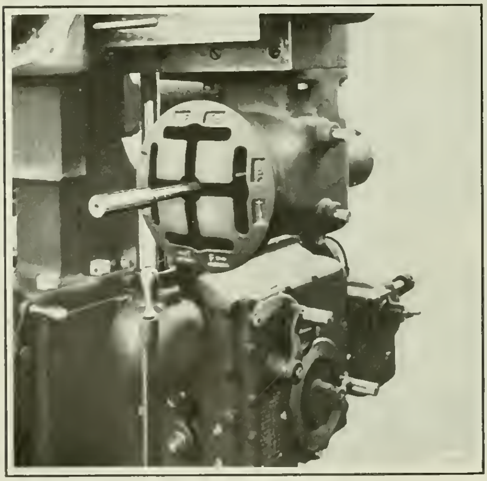

Fig. 3. Close-up View of the Colburn Single-lever Control for Head Feeds and Traverses

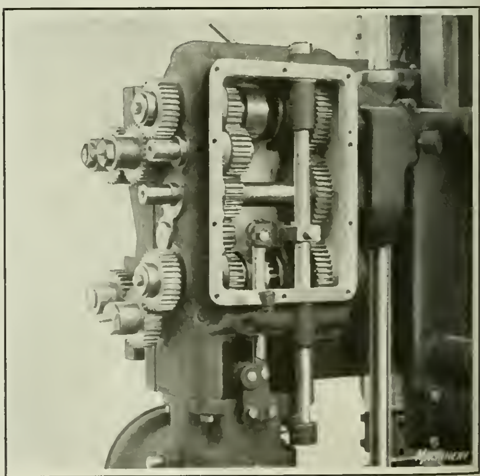

Fig. 4. Feed-clutch Gear-box with Covers removed to show Change-gears and Studs for Threading Gears

strains. A heavy guard protects the operator against injury from the revolving table. Twelve table speeds in geometrical progression are obtainable through sliding gears and positive clutches by shifting two levers at the right-hand side of the machine adjacent to the table. The inside lever operates the gears in a primary speed unit, and the outside lever operates the gears of a secondary speed unit.

The gears are shifted through a patented cam arrangement at the rear of the machine. The secondary speed unit is contained in a box in the main bed, which serves as a reservoir and should be kept supplied with about ten gallons of lubricating oil. The machine may be driven by a motor mounted on a bracket between the housings, through single pulleys and a large friction clutch, or by belt from a lineshaft through a single pulley. Hand-levers on each side of the machine at the front permit convenient starting and stopping. These levers automatically operate a brake, which enables the machine to be stopped instantly at a predetermined point.

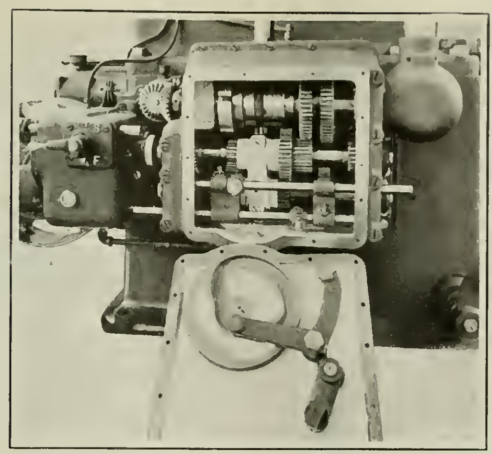

Fig. 5. Feed-multiplying Gear-box on Left-hand Side of Machine

Provisions for Lubricating

Care was taken in designing this machine to provide positive automatic lubrication throughout. The main driving gears and their bearings are lubricated by splash and spray from the oil reservoir previously referred to. Oil is also pumped to a cored reservoir in the top brace of the machine, whence it flows to the feed-boxes, primary table speed unit, table-spindle bearings, and cross-rail elevating mechanism. In each case, the oil passes through sight-feed oilers so that the operator can see whether or not the oil is flowing freely. The feed-clutch gear-boxes at the rear of each end of the cross-rail, one of which is illustrated in Fig. 4, are filled with oil to a certain level. Adequate oiling of the angular and vertical bearings of the table spindle is provided for. Oil is piped from the reservoir in the top brace to the edge of the angular bearing, and is then forced through the vertical bearings back to the reservoir in the bed. Overflow from the angular bearing keeps a supply of oil on the table gear and pinion, and also lubricates the pinion bearing.

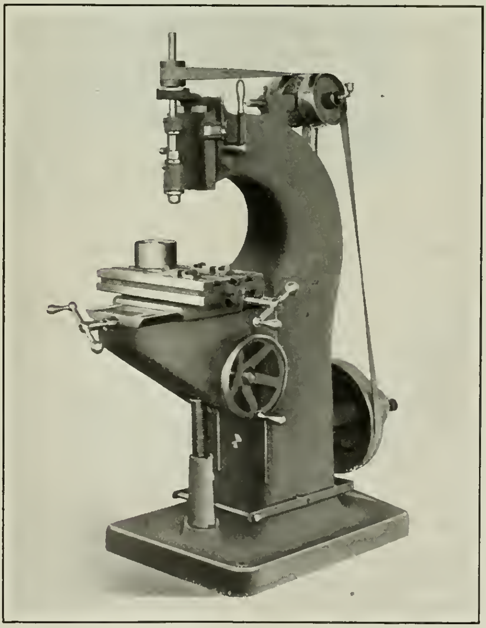
Thread-cutting and Other Attachments

Four, eight, and sixteen threads per inch can be chased without extra equipment, but when extra equipment is provided, standard threads from two to twenty-four per inch, including eleven and a half, can be cut. For cutting different threads, change-gears to suit the desired lead are mounted on the proper studs at the ends of the cross-rail, which may be seen in Fig. 4, and a lever on the feed-box is placed in the proper position. The machine may also be equipped with the following attachments: Revolving spindle center head, grinding spindles, cutting compound outfit, cross-taper and forming attachment, and pulley-crowning attachment.

The safety of the operator received due consideration in the designing of this machine. All moving parts on the ends of the cross-rail are enclosed, and the driving pulley and clutch are guarded. The various units are protected against overload.

BECKER HIGH-SPEED VERTICAL MILLING MACHINE

A demand for a vertical milling machine of the same size as the No. 2 machine built by the Becker Milling Machine Co., 677 Cambridge St., Worcester, Mass., but having higher spindle speeds, has led this concern to bring out the machine here illustrated, on which changes have been made that permit the use of speeds at least 50 per cent higher than on the former machine. It is practical to run the machine at a spindle speed of 6000 revolutions per minute, it being necessary, of course, to pay proper attention to oiling when running at such speed. With the maximum speed of 6000 revolutions per minute, two other speeds of 3240 and 1800 revolutions per minute are obtainable through the use of a three-inch spindle pulley, and three speeds of 3540, 1920, and 1060 revolutions per minute through a five-inch pulley. The necessary countershaft speed is 540 revolutions per minute.



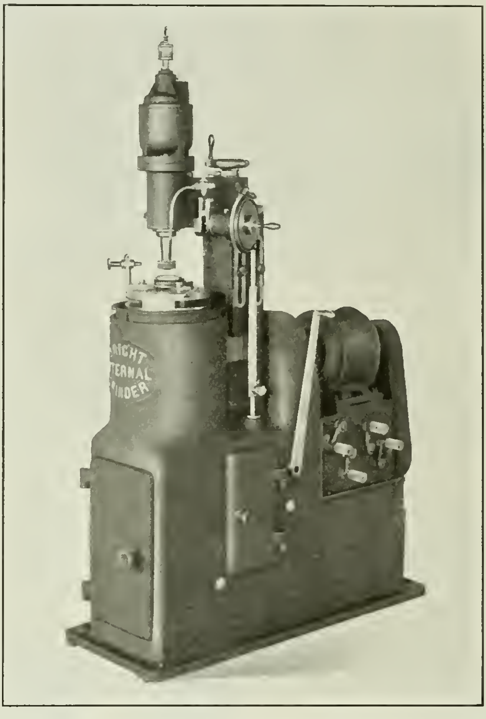
High-speed No. 2 Vertical Milling Machine brought out by the Becker Milling Machine Co.

The changing of the spindle pulleys is simple. It is merely necessary to lift the pulley on the machine by hand, away from the sleeve on which it is mounted, and substitute the other pulley. The belt slack is then taken up by means of the adjustable idler-pulley bracket. The machine is equipped with an auxiliary ball bearing to compensate for belt pull. Hardened steel thrust washers are provided for the spindle and the main bearing of this member is made of bronze and has a babbitt lining. The spindle is ground all over and carefully balanced. The spindle pulley and all rotating collars and nuts are also balanced so as to minimize vibration. Other improvements on the machine consist of a box knee and a steel chip-guard on the knee in front of the carriage, which protects the cross-feed screw.

BRIGHT INTERNAL GRINDING MACHINE

An internal grinding machine, on which the work is held in a chuck mounted at the top of a vertical spindle which both revolves and reciprocates in the same bearing, is being placed on the market by the Garvin Machine Co., Spring and Varick Sts., New York City. This machine is intended for grinding straight round holes in such parts as ball races and automobile transmission gears on a manufacturing basis. It is named after the inventor. The wheel-head swivels on an upright arm to bring the grinding wheel in contact with the surface to be ground and to permit a ready replacement of the work or measurement of the hole. The rated capacity of this machine is for holes up to 4 inches in diameter and 4 inches in length, and work up to 11 inches in swing.

The chuck spindle is supported at the lower end on a ball contained in a pocket at the upper end of the lift bar employed for reciprocating the spindle. The ball bears against hardened steel disks in both the spindle and the lift bar, and the pocket in which it is placed is sufficiently large to permit the ball to revolve freely and thus wear evenly. The spindle is driven through bevel gears from a shaft extending from the speed change-box at the rear of the machine. The gear which drives the spindle runs in a separate bearing and does not touch the spindle. It drives the latter through three sets of flexible keys made of spring steel, which slide in splines as the spindle travels up and down.



Bright Internal Grinding Machine which is manufactured by the Garvin Machine Co.

Driving by means of these keys eliminates any strains on the spindle, and because of this and the ball support, it is claimed that there is no pressure on this member, except that resulting from bringing the grinding wheel in contact with the work. This pressure is said to be negligible, and that a perfect film of oil is always maintained between the contact surface of the spindle and that of its bearing. The length of the spindle stroke is controlled by an adjustable crank arrangement in the base of the machine that is operated by means of a heart-shaped cam. The latter is driven through worm gearing by a second shaft extending from the speed-change box. The cam is designed to give the crank a straight-line action.

There are ten changes of stroke, ranging from 4 to 48 per minute, and five chuck-spindle speeds ranging from 100 to 385 revolutions per minute. The length of stroke may be adjusted while the machine is in operation. The load on the cam and gears is relieved by a counterweight. The chuck-spindle driving and reciprocating mechanisms are driven from a motor mounted on the speed-change box, power being transmitted through a silent chain, friction clutch and the speed-change box. Lubricant is automatically fed to the chuck spindle by a system which ceases to function when the machine is stopped.

The spindle of the grinding wheel is connected to the rotor of a vertical motor on top of the wheel-head. The rotor shaft has only one bearing which is located at its upper end. The lower end of the shaft is connected by a coupling to the grinding wheel spindle. This spindle runs in four ball bearings, which have an adjustment to compensate for wear. An extension for the wheel spindle adapts the machine to deep-hole grinding. The wheel spindle is driven at speeds ranging from 7500 to 12,000 revolutions per minute.

As previously mentioned, the wheel head is swiveled on an upright arm to bring the wheel in contact with the work. The wheel head is roughly set for a given job by means of a clamp bolt, and then fed to the work by rotating a feed screw held in a bracket attached to the housing in which the head arm slides. This feed screw has a total adjustment of ¾ inch. It contacts with a finished block on the side of the head, to which it is rigidly held to insure accurate feeding of the wheel. The feed screw is automatically advanced by means of a ratchet mechanism. The ratchet wheel has fine teeth about its periphery, each of which causes a 0.0001 inch advancement of the wheel, the wheel being fed forward at each end of the stroke. The height of the head is adjustable a distance of 6 inches by means of a vertical elevating screw operated through a handwheel.

When it is desired to remove or examine a piece of work, the machine is stopped almost instantly by pulling to the front, the long lever on the right side. Movement of this lever also raises the wheel-head arm and frees the head from its connection to the feed screw. The head may then be freely swung to the left through an arc of about 45 degrees. At the farthest position, it is held by means of a positive stop in direct line with the truing diamond, in which position the wheel may be conveniently dressed by operating the long lever backward and forward sufficiently to feed it up and down past the diamond. This truing device is always in a fixed position. A spring plunger relieves the head from any shocks in returning it into contact with the feed-screw. Water is pumped to the grinding wheel from a reservoir at the rear end of the housing. The machine is so designed that water or grit cannot be carried to bearings or working parts. The water is returned to the reservoir after serving its purpose. A guard may be raised to surround the chuck.

HORTON DIFFERENTIAL SCROLL CHUCK

Differential gearing incorporated in a wrenchless scroll chuck developed by the E. Horton & Son Co., Windsor Locks, Conn., for use in quantity production work on engine and turret lathes, permits speed of operation and a powerful grip on the work. This chuck may be operated by hand or by

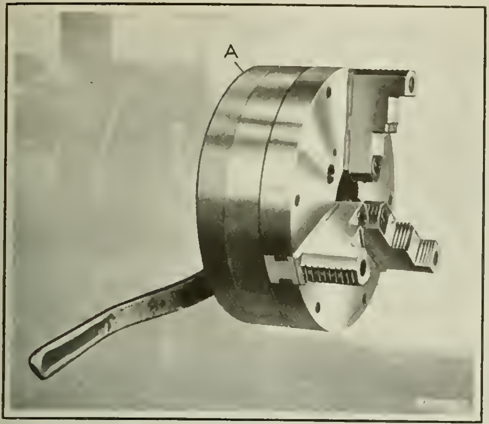


Fig. 1. Differential-geared Scroll Chuck designed by the E. Horton & Son Co.

power transmitted from the machine spindle during the revolution of the spindle before the tool begins to cut the work. The jaws are designed to grip work either on an outside or inside cylindrical surface, and are operated to and from the center of the chuck through five double spur pinions. A large ball bearing insures easy operation. The overhang is no greater than with scroll chucks of the usual design.

To operate the chuck, the knurled handwheel *A* in Fig. 1 is revolved until the jaws close on the work. Then the grip is tightened either by giving a quick push on the handwheel or by starting the machine and exerting a pressure on the lever. In opening the chuck, a quick pull on the handwheel releases the grip, after which the jaws can be run out to clear the work by giving a spin to the handwheel. The construction of the chuck will be understood by referring to Fig. 2. It will be seen that the handwheel carries the five double pinions previously referred to. These pinions mesh with a backing gear pinned to the chuck body and an internal gear on the reverse side of the scroll. The internal gear is different in pitch diameter from the backing gear. Therefore when the handwheel is revolved, the scroll is rotated by a powerful force on account of the differential action due to this difference in pitch diameters. One revolution of the handwheel causes the jaws to move approximately 1/32 inch radially, and opens the chuck 1/16 inch in diameter.

The arrangement for gripping and releasing the chuck by hand is an important feature. By providing for a slight rotation of the backing gear on the pins which hold it to the body, a small lost motion is imparted to the handwheel. This lost motion furnishes a hammer action that multiplies many times on the scroll, the actual pressure applied to the handwheel. The lever is bolted to the machine and carries a friction shoe which may be brought in contact with a surface on the inside of the handwheel. When it is desired to use power for gripping, the lever is employed to retard the handwheel while the chuck revolves. The chuck is now made in a 13-inch size, and 9- and 16-inch sizes are also to be made.

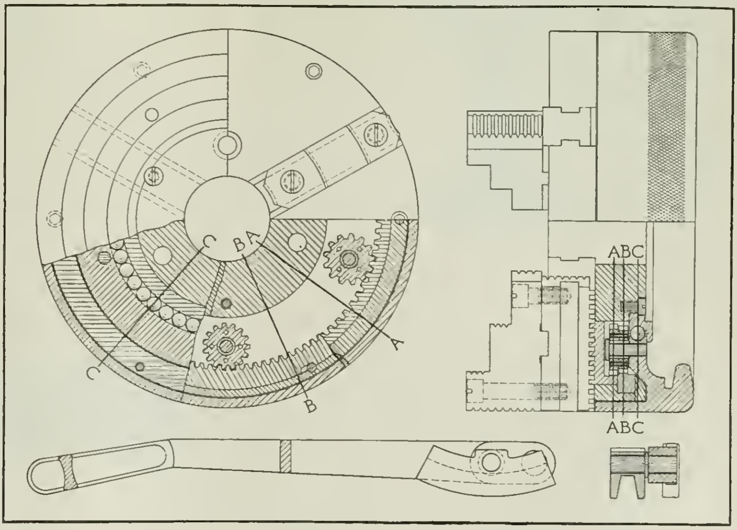

Fig. 2. Construction of the Horton Differential Scroll Chuck

"ETTCO" HIGH-SPEED TAPPING ATTACHMENT

The majority of taps that are broken in use break just after the hole has been tapped and the rotation of the tap has been reversed to withdraw it from the hole. Chips produced when a tap is fed into a hole stick to the wall of the hole, and when the tap is reversed, the heel of the flutes comes in contact with these chips. As these heels are not ground for cutting, the chips become clogged between the wall of the hole and the tap, and produce a strain sufficient to break small-sized taps. With a view to eliminating this source of trouble, the Eastern Tube & Tool Co., Inc., 594 Johnson Ave., Brooklyn, N. Y., has brought out a sensitive high-speed tapping attachment, as shown in Fig. 1, having a friction drive both for feeding and reversing the tap. A cross-sectional view of this attachment is illustrated in Fig. 2. The attachment has a capacity for tapping holes up to 3/16 inch diameter in steel, and up to ¼ inch diameter in cast iron and brass.

The shank of the tapping attachment is inserted in the spindle of a drilling machine, which may be run at any desired speed. In feeding the attachment, the chuck and the cone *A*, which is leather-faced on its inner and outer conical surfaces, remain stationary until the tap is brought into contact with the part to be tapped. An additional 1/16-inch movement of the machine spindle brings the cast-iron driving cone *B* into contact with the outer leather face of cone *A*. Cone *B* is fastened to the shank of the attachment, and causes cone *A* to drive the chuck spindle in the proper direction for tapping. The friction drive enables the speed of the tap to be regulated by varying the pressure applied to the feed-lever of the machine, which, of course, governs the amount of slippage between cones *A* and *B*.

Any undue resistance results in a complete slippage of the two cones, and so when the bottom of the hole is reached and the tap stops revolving, the operator readily observes that the tapping has been completed and raises the feed-lever of the machine. While this is being done, the chuck and cone *A* remain stationary until the machine spindle has been lifted 1/16 inch, which is sufficient to bring the cast-iron cone *C* into contact with the inner leather face of cone *A*. Cone *C* is driven through gearing from a ring gear on cone *B*, and revolves in the opposite direction to cone *B*. Therefore, the moment that cone *C* is brought into contact with cone *A*, the chuck spindle is revolved in the right direc-

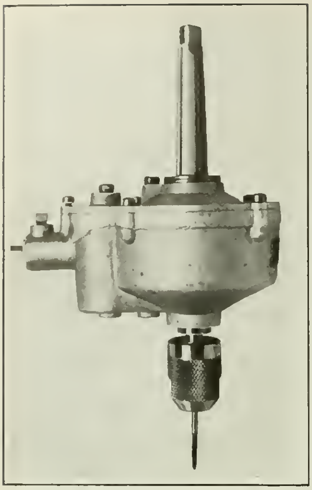

Fig. 1. Tapping Attachment made by the Eastern Tube & Tool Co., Inc.

tion for withdrawing the tap from the hole. In case chips cause the tap to stick during withdrawal, cone *A* will slip on cone *C* as previously mentioned, and the danger of tap breakage is averted.

Power is transmitted from cone *A* to the chuck spindle through an Oldham coupling *D*, which allows cone *A* to float sufficiently to insure a uniform contact at all times with the cast-iron cones. The reverse speed of the chuck spindle is twice the forward speed. The chuck is also manufactured by the Eastern Tube and Tool Co., Inc. It holds the taps by the square end and round shank with equal pressure, and has a slight float to allow a tap to follow the hole correctly. After the leather faces of cone *A* become glazed, the attachment is very sensitive and responds to any slight pressure, the cone slipping whenever the resistance to the tap is greater than normal. By making the housing from aluminum and the gears from a light alloy steel, the weight of the unit has been reduced to about 3¾ pounds. The distance

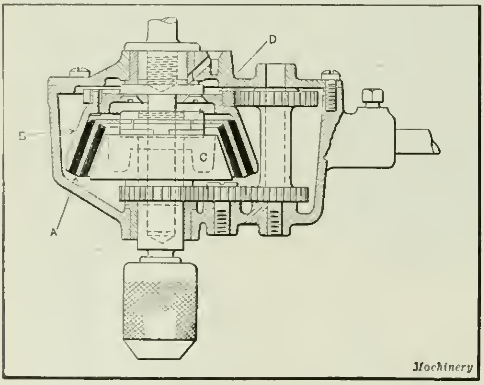

Fig. 2. Cross-sectional View, showing Construction of the "Ettco" Tapping Attachment

from the chuck nose to the end of the machine spindle is 5¼ inches. A rod inserted in a socket of the housing prevents the device from rotating during an operation.

VAN KEUREN MEASURING WIRE SETS

Sets of wires for measuring screw threads, profile gages, and angular surfaces, have been added to the line of precision measuring equipment manufactured by the Van Keuren Co., 362 Cambridge St., Allston, Boston, Mass. From the illustration it will be seen that wires of one size are contained in glass bottles, which protect them against rust and lessen the danger of breakage or loss. The wires are checked by light waves against standards certified by the Bureau of Standards. They are 1⅞ inches in length and lapped the full length to give a long life. Handles or suspension ends are not furnished unless desired.

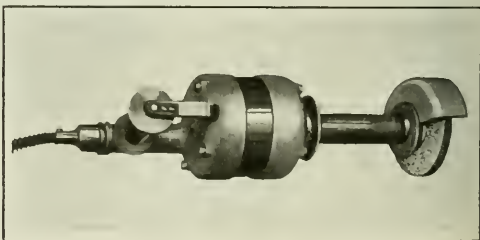
The wires furnished for thread measurement are known as "best size" wires, that is, they are of such diameter that they theoretically touch on the pitch line of a perfect thread. By using "best size" wires for each pitch of thread, the measurement of the pitch diameter is unaffected by any error of thread angle. This angle may be checked by taking a measurement with the next larger sized wire. Labels on the bottles give the wire diameter in hundred-thousandths inch.

Each label also gives the formula for determining the pitch diameter of a screw with wires of that bottle. To find the pitch diameter, subtract a given constant from the micrometer measurement over the wires in the thread. The set illustrated includes the common sizes of wires for threads from 6 to 36 pitch. It contains all the wires needed for the measurement of U. S. standard, S. A. E. and National coarse and fine threads, between these pitches. Additional sizes are made ranging from a ½-inch plug to wires 0.00641 inch in diameter for measuring 90-pitch threads.

Set of Measuring Wires introduced to the Trade by the Van Keuren Co.

FORBES & MYERS PORTABLE GRINDER

The motor supplied with the Model 35 portable electric grinder placed on the market by Forbes & Myers, 178 Union St., Worcester, Mass., is insulated with asbestos subjected to a patented treatment which binds its fibers into a tough but flexible mass that prevents the winding of the motor from burning out as a result of overload. The motor is of ¾ horsepower capacity, and resumes its normal speed quickly after having been slowed down by an overload. The bearings are self-lubricating, and may be quickly replaced when worn out. Electric shocks are avoided with this tool by grounding a wire to a water pipe or some other permanent

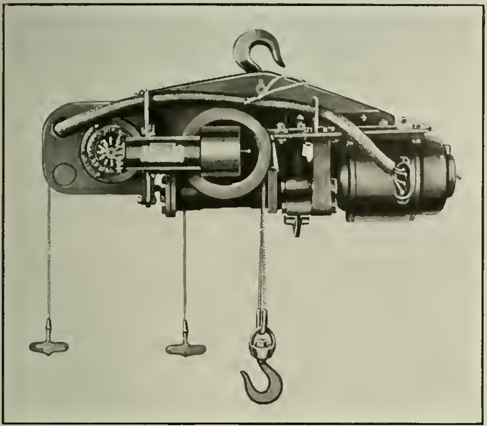


Model 35 Portable Electric Grinder produced by Forbes & Myers

ground. The controlling switch is located in the handle. Wheels 6 inches in diameter by 1 inch thick are standard for this tool, although thicker wheels may be used. The spindle speed is 3600 revolutions per minute.

"EVEREDY" ELECTRIC HOIST

A light-weight quick-speed electric hoist intended to replacing hand hoists in cases where speed is a factor has been added to the line of chain and electric hoists manufactured by the Reading Chain & Block Corporation, Reading, Pa. This hoist is known as the "Everedy" and is made in different sizes having capacities of from 500 pounds to 2 tons. It may be controlled either by a pendant cord or push-button switch, and may be provided either with a plain or geared

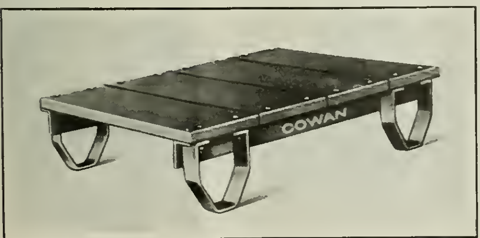


"Everedy" Electric Hoist which is a Product of the Reading Chain and Block Corporation

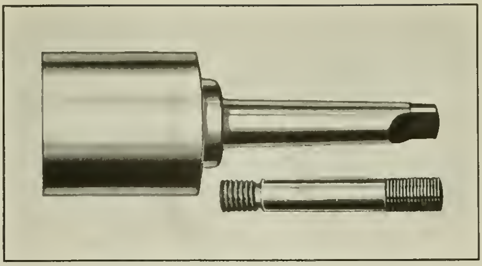
trolley or a hook suspension. The hoist has a motor-and-load brake which takes up its own ware. The rope drums have deep grooves that eliminate overloading and jamming. A special feature of the hoist is a patented positive up-and-down limit stop. All working parts are protected and arranged to run in heavy grease, to insure proper lubrication.

COWAN LIFT TRUCK SKID

For use with hand and electric lift trucks, the Cowan Truck Co., 16 Water St., Holyoke, Mass., has placed on the market a skid consisting of heavy pine planks bolted on two pieces of 2½ by 2 by 3/16-inch angle-iron, to which are attached four malleable iron legs. The construction of the skid is such that the platform cannot spread, sag, buckle or warp. The legs are both riveted and bolted to the angle-irons to insure a rigid connection. The skid is made in lengths from 24 to 80 inches, in widths from 24 to 48 inches, and in heights of 6½, 7½, and 9½ inches. Skids 40 to 80 inches long and 39 to 48 inches wide are also made 11½ inches high.



Hand and Power Lift Truck Skid made by the Cowan Truck Co.



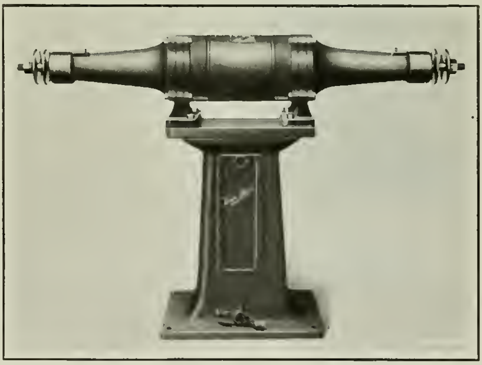
Jarvis Self-opening Stud Setter manufactured by the Geometric Tool Co.

JARVIS SELF-OPENING STUD-SETTER

The Jarvis self-opening stud-setter shown in the accompanying illustration is the latest addition to the line of small tools manufactured by the Geometric Tool Co., New Haven, Conn. This tool is simple in design and easy-working. A quick grip and ready release operate the jaws to and from the stud to be driven in place. This stud setter is regularly made in three sizes: The No. 1½ size has a capacity for studs up to ½ inch in diameter, and is regularly made with either a No. 2 or a 3 Morse taper shank; the No. 2 size has a capacity for studs up to 7/8 inch in diameter, and has a No. 3 or a No. 4 Morse taper shank; and the No. 3 size has a capacity for studs up to 1¼ inches in diameter, and has a No. 4 or a No. 5 Morse taper shank. Taper shanks other than those mentioned may also be furnished. Jaws of different size may be supplied for studs within the capacity of each setter.

VAN DORN HEAVY-DUTY BUFFING MACHINE

A heavy-duty buffing machine designed for large work requiring wheels or brushes twelve inches in diameter or over is the latest addition to the line of electrically driven ma-



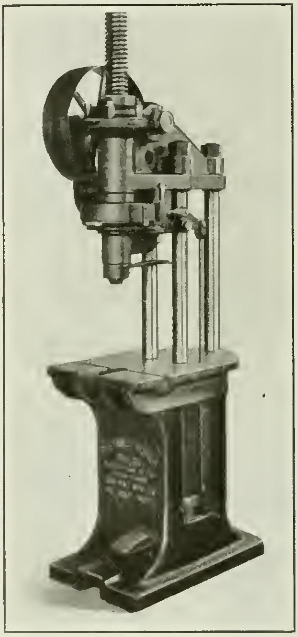
Six-horsepower Buffing Machine built by the Van Dorn Electric Tool Co.

chines manufactured by the Van Dorn Electric Tool Co., Cleveland, Ohio. There are extensions on both ends of the motor so that the brushes are about five feet apart; thus there is ample room for two operators. The buffing-wheel shafts are two inches in diameter inside the arm extensions where they are mounted in ball bearings. These bearings are enclosed in dustproof cages into which grease may be readily injected through four ports on top of the arms. Equalizing couplings are placed between the motor and the wheel shafts to correct any misalignment and thus eliminate vibration.

The motor is designed especially for this machine. It is of the polyphase induction type, and develops six horsepower under normal continuous operation, but has double that capacity under momentary overloads. The machine can be furnished for operation on two- or three-phase current having from 220 to 440 voltage. The current enters through a conduit hole in the rear of the pedestal, the fuses and switch being enclosed in the latter so that no electrical appliances are exposed. Starting and stopping of the machine is effected through the foot-pedal. Self-ventilation of the motor, which is ordinarily accomplished by a fan inside the motor, can be materially assisted in a dusty atmosphere by connecting the motor housing to a fresh-air supply pipe. This machine weighs approximately 700 pounds.

"FLEXIBLE" POWER PRESS

Flexibility or variation of the power applied on the work is the main feature of a power press developed by the General Mfg. Co., 255 Meldrum Ave., Detroit, Mich. The power may range from a few pounds to eight tons. This press is particularly adapted for straightening operations, pressing bushings in place, and assembling other parts having a press fit. The machine has a stroke of nine inches, and thus can also be used in push-broaching. The table has a fixed height of 30 inches. Three posts extend upward from the table, two of which are under tension and the third under compression.



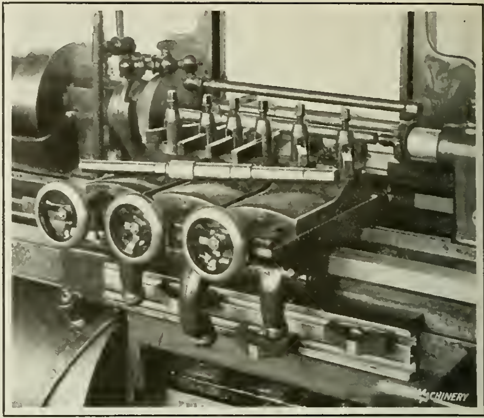
"Flexible" Power Press built by the General Mfg. Co.

The ram has a long-lead Acme thread and runs through a nut four inches long. Power is transmitted from the driving pulley to the ram through worm-gearing. The ram is driven at a constant speed in one direction, the nut turning with it until pressure is applied on the foot-pedal. Operation of this pedal closes an asbestos-lined brake-band on the nut. The ram then passes down through the nut until the pressure is released from the foot-pedal or until the pressure applied by the ram equalizes the pressure on the pedal. The return stroke is obtained through a spring at the top of the ram. The ram is raised immediately after an operation to the position in which the nut revolves about it.

The maximum height between the lower end of ram and table is 12 inches unless otherwise specified. The speed of the ram travel is 150 inches per minute with the pulley running at 300 revolutions per minute. End thrust of the ram is taken by a ball bearing placed between the nut and the main casting of the head.

PRATT & WHITNEY NECKING ATTACHMENT FOR AUTOMATIC LATHE

An automatic lathe with a magazine for feeding cylindrical parts to centers, between which they are held while being machined, was described in December, 1921, MACHINERY, shortly after the machine was developed by the Pratt & Whitney Co., Hartford, Conn. The accompanying illustration shows an attachment which has been brought out for use on this machine. This attachment is designed for squaring shoulders, necking turned surfaces prior to grinding, or for taking other cuts in which a cross-feed can be utilized.

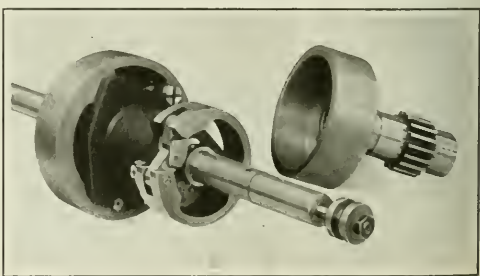


Pratt & Whitney Automatic Lathe fitted with Necking Attachment

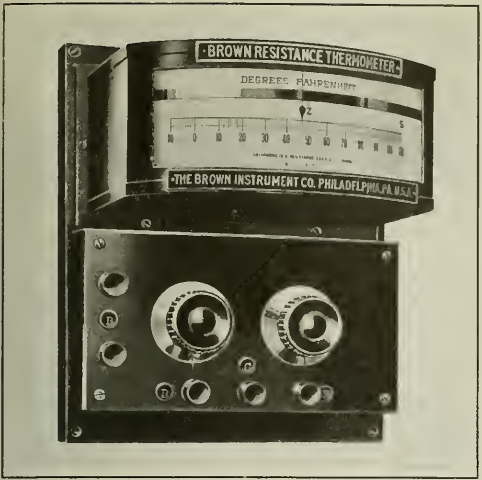
The attachment consists of several carriages which are substituted for the regular carriage. One, two, or three of the special carriages may be clamped in various positions to the front way of the bed. They carry tool-slides and may be provided with multiple toolposts. The cross-slides are actuated through the medium of rolls on arms attached to the carriages. These rolls come in contact with cams mounted on a carrier which is reciprocated longitudinally by the main feed-cam of the machine. The cams on this carrier can be adjusted to provide any sequence of cross movements, and it is possible to move all slides in unison. Adjustment for depth of cut is made on each carriage through its handwheel, which has a dial graduated to 0.001 inch. Suitable oil distribution is provided for all working parts. The different members of this equipment may be readily removed from the machine when the regular carriage is to be substituted.

GREAVES-KLUSMAN FRICTION CLUTCH

Geared-head lathes manufactured by the Greaves-Klusman Tool Co., Cincinnati, Ohio, are now equipped with an improved friction clutch in which the clutch ring is expanded on both sides instead of on only one side, as was the case with the clutch provided in the past. The expanders of the new clutch are located at the center of the ring, and apply a direct pressure. Eccentric studs of the levers provide for adjustment to maintain the same leverage at all times. This design eliminates twisting and springing of parts with the resulting wear. The driving hub is made in one piece, with a long bearing on the shaft and a long driving key. This clutch also has a wider face and is larger in diameter for some machine sizes than that previously made.



Greaves-Klusman Friction Clutch



Direct-reading Resistance Thermometer made by Brown Instrument Co.

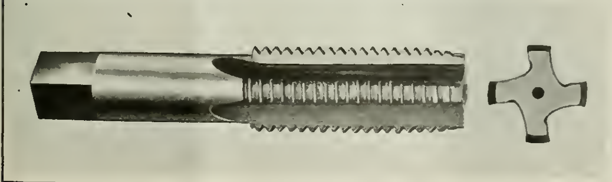
BROWN DIRECT-READING RESISTANCE THERMOMETER

In some heat-treating processes the temperature must be accurately known and maintained within close limits. For example, if the desired temperature is 820 degrees F., the low and high limits may be 750 and 900 degrees F., respectively. The accompanying illustration shows a direct-reading resistance thermometer brought out by the Brown Instrument Co., 4510 Wayne Ave., Philadelphia, Pa., to meet such conditions. The scale of this instrument could be graduated from 750 to 900 degrees F. for the example cited, in which case each division would be equivalent to 1 degree and afford accurate readings. The instrument may be furnished to cover a range of only 25 degrees F. The fundamental principle of the resistance thermometer is based on the well-known physical property of metals (with the exception of special resistance alloys) of change in resistance with change in temperature. This change in resistance can be accurately measured and a scale calibrated in temperature degrees. The bulb or coil of wire which changes in resistance is usually made of nickel for temperatures up to 300 degrees F., and of platinum for higher temperatures up to 1800 degrees F.

The left-hand knob of the instrument is turned to *Z* to check the zero reading, and to *S* to check the instrument with a standard resistance at the top graduation on the scale. The right-hand knob is used for adjusting the voltage. By means of a switch, the instrument can be connected to any number of resistance thermometer bulbs installed in different locations.

BATH "EASY-CUT" GROUND TAPS

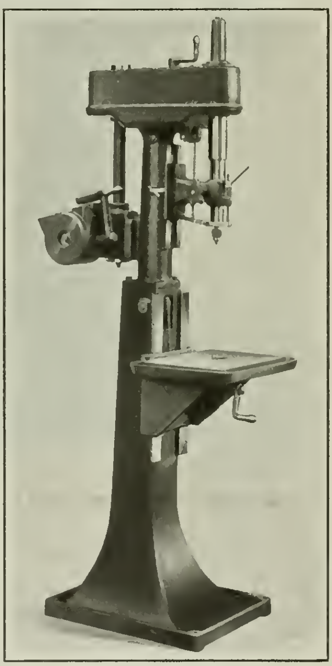
An improvement has been made in the line of "Easy-cut" ground taps manufactured by John Bath & Co., Inc., 8 Grafton St., Worcester, Mass., (described in May, 1921, MACHINERY) by changing the design of the flutes. This new design is known as the "sharpening face" flute. From the illustration it will be seen that each flute has a projecting face having an under-cut clearance that permits the tap to be resharpened without changing its size, until it is worn out. Another advantage is that the cutting face can be ground to any angle or concave to give the desired rake for the kind of material being tapped. The sharpening face is narrow and is the only part of the flute that is finished. The rear side of each flute has a hook for removing chips from the threads of the work when the tap is reversed. This eliminates danger of tooth breakage when the tap is being withdrawn from the hole. The new style flute has a standard width of land and sufficient chip room. Taps are made of both high-speed and carbon steel and may be driven by hand or power.



"Sharpening-face Flute" Tap made by John Bath & Co., Inc.

FOSDICK SENSITIVE DRILLING MACHINE

The principal feature of the new "Superspeed" drilling machine recently placed on the market by the Fosdick Machine Tool Co., Cincinnati, Ohio, is the speed-change arrangement. With this arrangement a single turn of a handle causes the tension on the driving belt to be automatically released and the belt to be shifted first from the larger step of one cone pulley to the next smaller step, and then from the smaller to the next larger step of the second cone pulley. Tension is then automatically applied to the belt. This machine is shown in the accompanying illustration. It is built in both bench and pedestal types in combinations having from one to eight spindles, and has a capacity for driving drills up to 1/4 inch in steel. With the driving pulley running at 1750 revolutions per minute, three spindle speeds of 5700, 8000, and 12,000 revolutions per minute, respectively, are available. However, other speeds may also be provided to meet conditions.



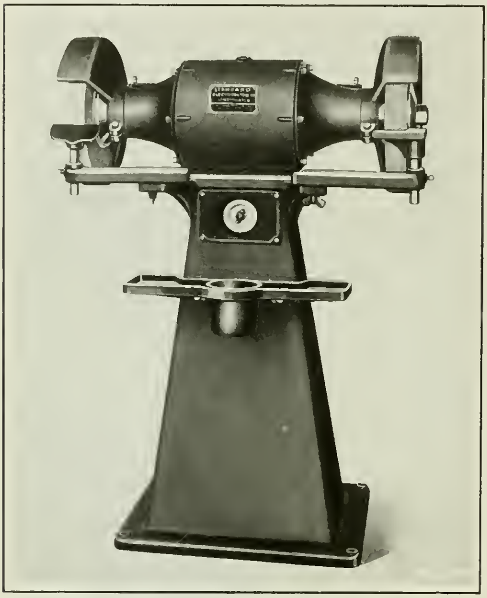
Fosdick "Superspeed" Drilling Machine

All revolving members are equipped with annular ball bearings and dustproof metal oil containers, the only revolving member exposed being the drill chuck. The drive is through spiral gears. The table on the pedestal machine is of the quick-acting counterbalanced type with a clamping handle at the front, and has a traverse of 10 inches. This table, as well as that of the bench machine, is surrounded with chip and lubricant channels. The head has a vertical traverse of 6 inches, and is counterbalanced to prevent it from dropping when unclamped. The spindle has a feed of 3 inches, and may be automatically stopped at any point within this range. An adjustable gravity counterbalance may be set to return the spindle automatically.

The position of the feed-lever may be adjusted to suit the convenience of the operator. Opposite the feed-lever is a quick-return handwheel. The belt guard is made of aluminum. Both the belt and shifter may be positioned to receive the driving belt at any angle. A ½-horsepower motor can be mounted on the machine for either a belted or a direct-connected drive. The spindle is provided with a No. 1-A Jacobs drill chuck. The bench-type machine weighs about 225 pounds, and the pedestal type, 465 pounds.

STANDARD ELECTRIC GRINDER

A two-horsepower alternating-current grinding machine, made in both bench and pedestal types for grinding light or heavy work, has recently been added to the line of products manufactured by the Standard Electric Tool Co., Cincinnati, Ohio. The machine is fitted with a tool tray, water pot and tool-rests, as illustrated. The controlling switch is within easy reach of the operator. One coarse and one fine wheel are furnished with each tool, the two wheels being 12 inches in diameter and 1½ inches face width, with a 1-inch bore. The wheels are located a sufficient distance from the body of the motor to facilitate the grinding of large or irregular parts. Both the bench and pedestal types are made for operation on either 110-, 220-, or 440-volt, two- or three-phase, 60-cycle, alternating current.



Grinding Machine made by the Standard Electric Tool Co.

GAMMONS-HOLMAN REAMER

An expansion hand reamer known as the "Parob" on which each cutting edge is followed and preceded by another which cuts at a different angle relative to the axis of the reamer has been placed on the market by the Gammons-Holman Co., Manchester, Conn. The design of the cutting edges eliminates chatter during an operation and enables holes having a keyway or oil-groove to be reamed satisfactorily. The reamer is expanded by means of a screw-driver, the expanding device being protected against accidental adjustment. It is so located within the pilot that a reamer may be ground on its own centers with the expanding device in place.

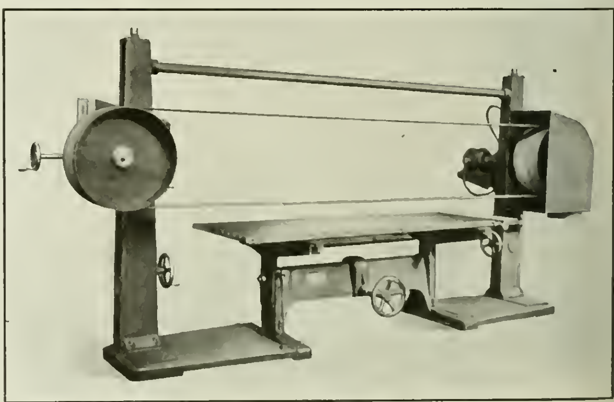
"Parob" Expansion Hand Reamer manufactured by the Gammons-Holman Co.

A special feature of this tool is an oil-hole that leads from the shank to the inside of the reamer and is connected with slots in the flutes. This provides a convenient means of delivering cutting lubricant to the work. The pilot is amply long for most jobs but pilots of special length may also be furnished. This reamer is particularly adapted for reaming wrist-pin bearings in automobile pistons. It is also made in multiple series for aligning bearings too far apart for standard reamers, or of different diameters. Each section of a multiple-series reamer has a separate adjustment. The reamer is regularly made in sizes from ½ to 1½ inches in diameter.

OLIVER BELT SANDER

The sanding or polishing of wooden pieces required in building large patterns may be conveniently accomplished on a No. 183 self-contained belt sander introduced to the trade by the Oliver Machinery Co., Grand Rapids, Mich. The machine may also be used for polishing metal surfaces. The arms of one pulley are guarded, and the other pulley is entirely enclosed by an exhaust hood. Both pulleys are rubber faced and run on ball bearings. The table top also runs on ball bearings. The table has a vertical adjustment of 14 inches on two uprights connected by a heavy brace, this adjustment being obtained through a screw, gears, and a rack. The horizontal travel of the table is 36 inches, and its working surface is 96 inches long by 32 inches wide.

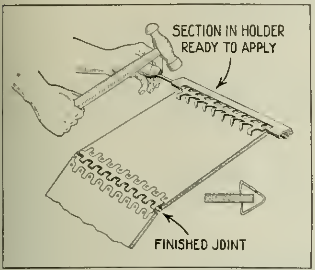
When the machine is motor-driven, a slow-running motor may be direct-connected to the driving shaft, whereas a high-speed motor would be geared to this shaft. The pulley should be run at a speed of about 600 revolutions per minute. Sanding belts about 31 feet long and up to 10 inches in width may be used.



No. 183 Self-contained Belt Sander brought out by the Oliver Machinery Co.

FLEXIBLE STEEL BELT LACING

Flexible steel lacing for tape, fabric, and light leather belts up to 5/32 inch in thickness is being manufactured by the Flexible Steel Lacing Co., 4622 Lexington St., Chicago, Ill. The method of fastening the ends of a belt together by this lacing may be seen in the accompanying illustration. In addition to smoothness of belt running and flexibility of the joint, the advantages that are claimed for this lacing are as follows: A separable connection, the possibility of running either or both sides of the belt in contact with pulleys, quick application, and the necessity of providing only half a joint when a belt must be shortened.

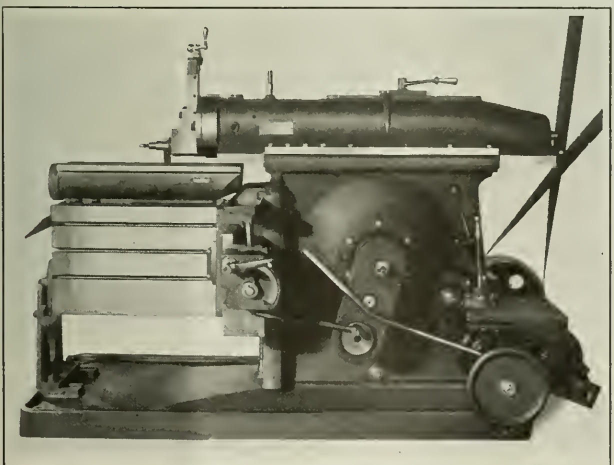


Belt Lacing made by the Flexible Steel Lacing Co.

KELLY HEAVY-DUTY CRANK SHAPER

A shaper designed for the heavy work handled in railroad and forge shops has been placed on the market by the R. A. Kelly Co., Xenia, Ohio. This machine is similar in many respects to a line of shapers made by the same company, which was described in June, 1920, MACHINERY. The new machine has a 32-inch stroke, a vertical table movement of 12½ inches, and a cross traverse of the table of 30 inches. The table is of the swivel type.

The cross-feeding mechanism is simple and entirely enclosed in a box. The direction of the feed is controlled by the straight knurled lever on top of the box, and the amount of feed by the lever on the side of the box. The feeding mechanism cannot be operated during the cutting stroke of the ram. No adjustment is necessary in order to raise or lower the cross-rail, except to loosen and retighten the clamping studs on the cross-rail. The gear-box is designed along the lines of an automobile transmission. It has four speed changes, which are engaged through a ball lever on top of the box. A clutch and brake are controlled by the long lever at the front of the machine. The ram may be brought to a stop at any desired point by the operation of this lever.

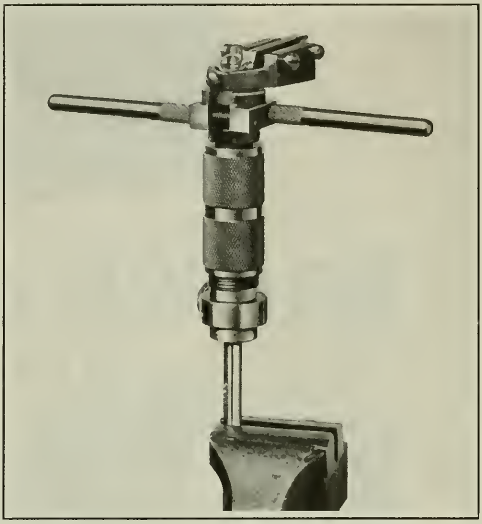


Railroad and Forge Shop Crank Shaper brought out by the R. A. Kelly Co.

When equipped for a motor drive, a bracket is bolted to pads on the back of the shaper for supporting the motor, and a gear is mounted on the driving shaft instead of the pulley. All machines are built so that motor drive may be easily applied, and a gear-box may also be quickly installed on a cone-driven machine. All gears are helical and all slide surfaces are provided with felt wipers. A guard on the table prevents chips from falling on the bearing of the table support. A guard is also placed over the elevating gears, and on this guard are cast directions for elevating and lowering the table. The weight of the machine is about 6500 pounds.

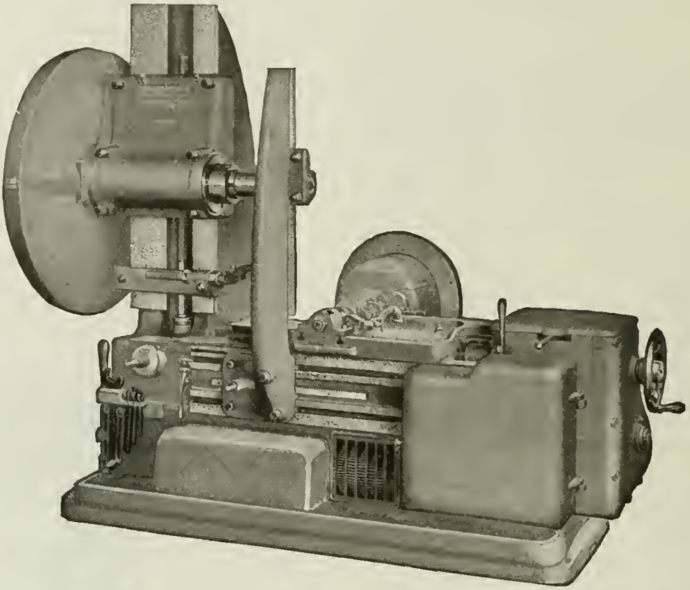
RAMSDELL HAND-VISE "LATHE"

Repairmen in general will be interested in a portable device by means of which studs, set-screws, cap-screws, and special screws, and pins may be produced accurately from bar stock. Coil springs may also be wound to any desired pitch with this device. It is known as the hand-vise "lathe," and is made by the Campbell Mfg. Co., Slater Building, Worcester, Mass. In the illustration it is mounted on a piece of bar stock and provided with a turning tool which is turning down one end of the stock. The tool is fed by turning the knurled member. The body of the device is held in position on the work by a thumb-screw.



Hand-vise "Lathe" placed on the Market by the Campbell Mfg. Co.

In addition to the parts illustrated, the equipment furnished with this device includes knurling tool, spring-winding details, S. A. E. taps and dies, spacers, and centering bushings. The turning tool-holder is so constructed that the die for a threading operation may be fitted in the upper part of the holder and a centering bushing in the lower part. The width of the centering bushing is sufficient to hold the stock central with the die while being threaded, and prevent the cutting of the thread off center. Centering bushings from ¼ to 1 inch in diameter, varying in size by 1/16 inch, are furnished with the set. Bar stock up to 1 inch in diameter can be accommodated, which enables hexagon-head screws up to ⅝ inch to be made. All wearing parts are casehardened.



BROWN & SHARPE
AUTOMATIC
GEAR CUTTING MACHINES

For the Accurate Duplication of High-Grade Gears

The accuracy and precision of Brown & Sharpe Automatic Gear Cutting Machines are important factors in accurately duplicating high-grade gears. The high quality of these machines takes on an added importance with the introduction of the Ground-Form Gear Cutter mentioned on the opposite page. The full benefits of these Ground-Form Cutters are assured by using them on Brown & Sharpe Gear Cutting Machines whose highly accurate indexing mechanism gives the uniformity in spacing essential for the duplication of accurate gears.

The extremely accurate worm wheel used on these machines is of large diameter in proportion to the diameter of the work, insuring accurate spacing of the gear teeth. The indexing mechanism operates without shock, has a positive start and stop, and is securely locked for each tooth space.

These high grade machines are built by men whose one thought is to get things "right." Every detail of construction is subjected to rigid inspection and the machines leave our plant ready for a long life of accurate production.

Send for Catalog No. 137 describing these machines

Accuracy of Form
Duplication of Accuracy
Increased Production

—the three outstanding features of the new

BROWN & SHARPE GROUND-FORM GEAR CUTTERS

(from 1¾ to 12 pitch inclusive)

ACCURACY of form—the primary requirement in precision gear cutting—is assured by the grinding of the tooth form—correcting all hardening distortions.

DUPLICATION of accuracy in different cutters through this positive control of form gives the user of cutters further ability to duplicate this accuracy in the finished gears—this continued accuracy and uniformity which makers of gears strive to maintain.

INCREASED production, due to the freer cutting action and keener cutting edges of these cutters, has been proved by actual tests to be surprisingly great. The freer cutting action, which is largely responsible for this increased production, is due to each tooth doing its share of the cutting, for the grinding of the form has so corrected any hardening distortions that no single tooth or group of teeth can do the major part of the work—each must do its share. Consequently the finish is correspondingly improved and cutter wear greatly reduced.

As to cost, these ground-form cutters necessarily list somewhat higher than those with the unground form but their ability to produce more and better gears per sharpening of the cutter will affect a pronounced saving in ultimate cutter cost—they mean high cutter economy from all angles, both as to quality and quantity of the gears produced.

BROWN & SHARPE MFG. CO.

Providence, R. I., U. S. A.

CHESTERFIELD CUTTING-TOOL METAL

An alloy consisting mainly of nickel, cobalt, and tungsten, which is non-magnetic and non-corrosive, is now being introduced to the trade by the Chesterfield Metal Co., 261 St. Aubin Ave., Detroit, Mich. It is sold in square, flat, and round bars for cutting into tool bits. One feature of this alloy is its extreme hardness, which is retained even when the friction of a cut is so severe as to bring the tool to a red heat. Chesterfield metal derives its hardness from the alloying process by which it is produced, and so cannot be tempered or annealed. This eliminates the danger of burning the cutting edge in dressing a tool.

The metal is cast in molds into assorted standard sizes. It is too hard to cut except by grinding, and so the bars in which it is cast are first nicked with a grinding wheel and then broken to the desired length for use. Tool bits made from the metal may be used in various commercial tool-holders or they may be welded to a machine-steel shank. Blades may also be made from the metal for inserted-tooth milling cutters. In a demonstration, a cast-iron disk 15 inches in diameter was rotated at a peripheral speed of about 600 feet per minute, and a cut 1/8 inch deep taken by a tool made from the alloy at a feed of 1/32 inch per revolution. While the cut was being taken the chips came off red-hot and the tool point was also red-hot, but the tool was apparently as good as ever at the end of the cut.

NEW MACHINERY AND TOOLS NOTES

Portable Drill Stand: A. H. Peterson Mfg. Co., Milwaukee, Wis. A portable stand designed to hold rigidly at any angle, the "Hole Shooter" portable electric drill manufactured by this concern. When placed in a perpendicular position, the equipment is suitable for use as a bench drilling machine, and when placed in a horizontal position, it is especially adapted to grinding or buffing. Bristle wire brushes, rotary taper files, special buffers, and circular saws are also made for use with this drill.

Electric Etching Pencil Outfit: Luma Electric Equipment Co., 405 Spitzer Bldg., Toledo, Ohio. An electric etching outfit consisting of two major units—a magnetic table and a pencil. Its chief uses include etching or writing on hardened steel, demagnetizing steel, annealing, and soldering. Work which has been placed on a magnetic chuck is demagnetized by simply passing it across the table of the outfit while the current is turned on, and tools or bars may be magnetized in the same way. For annealing, the pencil point is replaced by one made of carbon, and the cord of the pencil is attached to a second connection. The carbon point is also used for soldering.

NUMBER OF EMPLOYES IN THE MACHINE TOOL INDUSTRY

According to a report of the Bureau of Census, there were approximately 61,700 persons engaged in the machine tool industry in 1919. Of this number 2333 were salaried officers, superintendents, and managers, 6186 clerks, etc., (including men and women), and 53,111 wage earners, the latter being an average number. The state of Ohio had 13,855 wage earners (average number) or 26.1 per cent of the total number in the United States. Rhode Island was next in rank with 7169 wage earners, or 13.5 per cent of the total. The accompanying table gives the average number of wage earners in twelve of the most important machine tool building states. This table shows how the total number in each state is divided in regard to the prevailing working hours. The hours for most wage earners in the machine tool industry (39 per cent of the total number) are between 48 and 54 hours per week. About 29 per cent work 48 hours per week, 19 per cent between 54 and 60 hours per week, 10 per cent 54 hours, 2 per cent between 44 and 48 hours, one-half of one per cent 44 hours or less, and one-fifth of one per cent 60 hours per week. The total number of establishments in the United States directly engaged in the production of machine tools during the year 1919 was 403, and the total value of the products, $212,400,000.

AVERAGE NUMBERS OF WAGE EARNERS IN THE MACHINE TOOL INDUSTRY DURING 1919, BY STATES AND BY PREVAILING HOURS OF LABOR PER WEEK

State	Wage Earners, Total Average Number	Per Cent of Total for U. S.	Numbers of Wage Earners according to Prevailing Hours of Labor							Number of Establishments

INDUSTRIAL ADVERTISING CONFERENCE

In connection with the convention of the Associated Advertising Clubs of the World to be held in Milwaukee, Wis., June 11 to 15, an industrial advertising conference will be held which will deal entirely with this class of advertising. In connection with this conference, there will be an exhibition of industrial advertising, which will include complete campaigns of general advertising, business paper advertising, letters, broadsides, folders, and catalogues as well as single advertisements. Individual photographs, drawings, and paintings for advertising purposes will add to the attractiveness of the exhibition. Those interested in this part of the work of the conference should communicate with A. K. Birch, advertising manager, Allis-Chalmers Mfg. Co., Milwaukee, Wis. The program for the industrial sessions, of which Keith J. Evans, advertising manager of Joseph T. Ryerson & Son, Chicago, Ill., is chairman, will include a great many papers of interest to industrial advertisers.

MEETING OF THE AMERICAN SOCIETY FOR TESTING MATERIALS

The twenty-fifth annual meeting of the American Society for Testing Materials will be held in Atlantic City, N. J., during the week of June 26. There will be twelve business sessions, at which a number of interesting subjects will be considered, among which are the following: Metallography and corrosion of non-ferrous metals; wrought, cast, and malleable iron; steel; impact testing of materials; and methods of testing fatigue of metals.

ONE LEVER—

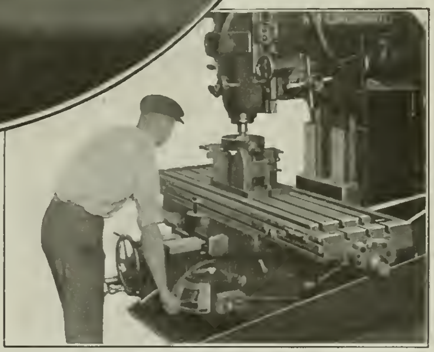
There are other exclusive features on these Millers it will pay you to know about—Write for Catalog.



The Feed Change Lever is Always at the Operators Finger Tips

The Cincinnati Milling Machine Co., Cincinnati, Ohio

OBITUARIES

William A. Greaves, president of the Greaves Machine Tool Co., Cincinnati, Ohio, died April 18, aged sixty years. Mr. Greaves was born in Cincinnati, Ohio. In 1889 he organized the firm of Greaves-Klusman & Co., in association with H. H. Klusman, to manufacture lathes. Later he retired from this firm, and with his three sons organized the Greaves Machine Tool Co. in Cincinnati. He is survived by his widow and three sons.

J. Ryan, for eighteen years manager of the Paris office of the Potter & Johnston Machine Co., of Pawtucket, R. I., died on the first of last May. Mr. Ryan was a man of great energy, a skilled mechanic, with a wide acquaintance among French engineers, including government officials, which enabled him to place enormous orders for Potter & Johnston machines during the war, that firm being generally credited with having made the largest sales in France of any one type of machine tool. Mr. Ryan had been in failing health for over a year, and his death will be a great loss to the company with which he was connected for so long a time.

LAROY S. STARRETT

Laroy S. Starrett, president of the L. S. Starrett Co., Athol, Mass., died of pneumonia at his winter home in St. Petersburg, Fla., on April 23. He lived to within two days of his eighty-sixth birthday. Mr. Starrett was born in China, Me., on April 25, 1836.

He was brought up on a farm and received his education in the country schools. His career was a remarkable one, starting among the hardest conditions of life and ending with marked success. At an early age he began to show a keen interest in the mechanical line, and was constantly busying himself with tools. When he was seventeen he left the farm and went to Newburyport, Mass., to work in a machine shop, and in 1866 he started his first machine shop in that town. In 1868 the Athol Machine Co. was established to manufacture his inventions. Mr. Starrett subsequently suffered reverses and lost control of that concern, but he was undaunted, and in 1880 began the manufacture of the well-known Starrett line of machinists' tools which has met with such marked success. He gradually built up a large business and later regained control of the Athol Machine Co. He also founded the Union Twist Drill Co. Mr. Starrett was a public-spirited man, and the prosperity of the town in which he lived was due, in a large measure, to his activities.

WILLIAM GLEASON

William Gleason, president of the Gleason Works, Rochester, N. Y., died at his home in Rochester, May 24. He was eighty-six years old, having been born in Tipperary County, Ireland, in 1836. He came to America at the age of fifteen, and served a machinist apprenticeship in Rochester. Later he went to Hartford, Conn., where he was employed in the Colt Armory during the Civil War. In 1865, Mr. Gleason returned to Rochester and opened a machine shop. Soon afterward he went into partnership with John Connell and James S. Graham under the name of Connell, Gleason & Graham, building machine tools and woodworking machinery. This partnership was dissolved in 1873 when Mr. Gleason went with the Kidd Iron Works, which he took over in 1875. Under the name of the Gleason Works the business has steadily grown from that time on, and wherever machine tools are used Mr. Gleason is known as the inventor of the bevel gear-cutting machines that bear his name. He was president of the Gleason Works up to the time of his death, although in his later years most of the business was administered by his sons, James E. and Andrew Gleason, who are vice-presidents. He is also survived by his wife and two daughters, Kate and Eleanor Gleason.

PERSONALS

Arthur Jenner, factory superintendent of the Noiseless Typewriter Co., Middletown, Conn., has resigned, and is planning to take a trip to Europe, returning about July 20.

Walter F. Rogers, of Southbridge, Mass., formerly with the Norton Co., Worcester, Mass., is now associated with the selling organization of the Reeves Pulley Co., Columbus, Ind.

Frank W. Adams, Jr., formerly western representative for C. E. Johansson, Inc., Poughkeepsie, N. Y., is now sales manager for the Steel Products Engineering Co., Springfield, Ohio.

John A. Johnson has been appointed works manager of the K. & F. Mfg. Co., 208 N. Wells St., Chicago, Ill., engineers and tool builders. Mr. Johnson has had a wide experience in the metal line.

L. S. Love, formerly vice-president and general manager of Barbour, Love & Woodward, New York City, has resigned his connection with that company. No announcement of Mr. Love's plans for the future has yet been made.

Malcolm Grant has joined the selling organization of the Black & Decker Mfg. Co., Towson Heights, Baltimore, Md., and will cover the state of Ohio, with the exception of the corner that takes in Cincinnati and Dayton. His headquarters will be at the Cleveland office, 2030 E. 22nd St.

Marvin E. Monk has been appointed assistant sales manager in charge of general sales of the U. S. Ball Bearing Mfg. Co., Chicago, Ill. Mr. Monk was formerly special sales engineer for Manning, Maxwell & Moore, Inc., of New York City. J. J. Torpey will continue as assistant sales manager in charge of bearing distributors.

R. M. Barwise who has been eastern representative of the Diamond Chain & Mfg. Co., Indianapolis, Ind., for the last twelve years, has opened an office and store-room at 18 Hudson St., near Reade, New York City. Mr. Barwise will act as distributor of Diamond chains, and of the gears and sprockets made by the Philadelphia Gear Works.

Carl G. Schluederberg, executive assistant to the manager of the supply department of the Westinghouse Electric & Mfg. Co., East Pittsburg, Pa., has been elected president of the American Electro-Chemical Society. Mr. Schluederberg has been very active in American electro-chemical circles and has done considerable research work along these lines.

C. M. Hall, formerly in charge of the New York territory for the Dodge Transmission Co., has become associated with the Black & Decker Mfg. Co., Towson Heights, Baltimore, Md., and will have charge of the territory that includes Indiana, Kentucky, and that corner of Ohio that takes in Cincinnati and Dayton. Mr. Hall's headquarters will be in Indianapolis.

C. G. d'Ugglas, formerly assistant chief engineer with the Cleveland Machine & Mfg. Co., Cleveland, Ohio, is now associated with Williams, White & Co., Moline, Ill., in the capacity of assistant chief engineer in charge of the power press division. Mr. d'Ugglas is a mechanical engineer. He came to this country from Sweden about ten years ago, and has been connected most of the time since he has been here with the manufacture of power presses.

Joseph F. Keller, of Brooklyn, N. Y., was awarded the Edward Longstreth medal by the Franklin Institute at its April meeting, for his automatic die-cutting machine. This medal was also awarded to Samuel T. Freas, of Trenton, N. J., for an interlocking tooth saw, and to Charles F. Wallace and Martin F. Tiernan of the firm of Wallace & Tiernan, Newark, N. J., for their apparatus for the distribution of liquid chlorine for water purification.

J. Martin Duncan of the Detroit Steel Casting Co., Detroit, Mich., has been promoted to the position of general sales manager. Mr. Duncan's previous work has been that of following up every important shipment to its destination, to see how the castings were applied, and to ascertain whether more satisfactory results could be obtained by a closer cooperation between the management and the user. He is succeeded in this work by E. R. Young. Mr. Allen, formerly sales manager, is now assistant general manager.

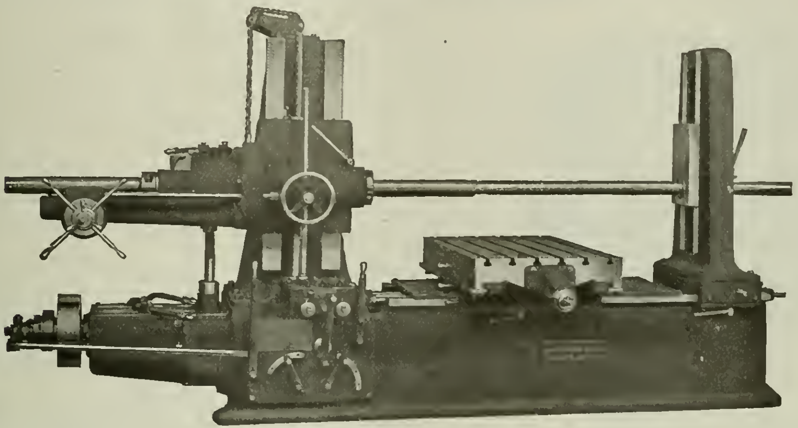
Ambrose Swasey, president of the Warner & Swasey Co., Cleveland, Ohio, was elected to membership in the National Academy of Sciences at the recent annual meeting in Washington. Members of the academy are grouped into committees of mathematics, astronomy, physics, engineering, chemistry, etc. The honor was conferred upon Mr. Swasey on account of his achievement and interest in the design and construction of great telescopes and other scientific instruments of precision. He established the Engineering Foundation and is an honorary member of a number of leading American and European scientific and engineering organizations, as well as an officer of the Legion of Honor of France. He is also a member of the National Research Council, which was organized in 1916 at the request of President Wilson, under the charter of the National Academy of Sciences.

Mr. MANAGER:

This is addressed to YOU.

A good many foremen and superintendents have told us that the men always prefer to use the

"Precision" BORING, DRILLING & Milling Machine



Why do the men prefer to use it? Because they want to *make a record,* and they can make it easier and quicker by using the *"Precision"*.

The reason that they want to make a record is that they want to make *more money* and they know that they must make a record first.

A record by the man is also a record for the foreman and the superintendent, and a record for the works.

A record for the works is a record for the *manager* and the manager doesn't object to more money either.

It is up to the manager to buy the kind of machines that will allow the record to be made—the *Precision* is *it*.

WE ALSO MAKE THE

COMING EVENTS

June 5-9—Annual convention and exhibit of the American Foundrymen's Association and allied societies in Rochester, N. Y. Secretary C. E. Hoyt, Marquette Bldg., 140 S. Dearborn St. Chicago, Ill.

June 14-21—Annual meeting of the Mechanical Division of the American Railway Association in Atlantic City, N. J. Secretary V. R. Hawthorne, 431 S. Dearborn St., Chicago, Ill.

June 15-24—International exhibition of foundry equipment and materials in Birmingham, England, in connection with the annual convention of the Institution of British Foundrymen.

June 20-24—Summer meeting of the Society of Automotive Engineers at White Sulphur Springs, W. Va. Chairman of Meetings Committee, C. F. Scott, 29 W. 39th St., New York City.

June 26-30—Twenty-fifth annual meeting of the American Society for Testing Materials in Atlantic City, N. J.; headquarters, Chalfonte-Haddon Hall Hotel. Secretary C. L. Warwick, 1315 Spruce St., Philadelphia, Pa.

August 28-September 2—Annual Safety Congress of the National Safety Council in Detroit, Mich. Secretary S. J. Williams, 168 N. Michigan Ave., Chicago, Ill.

September 11-16—Eighth national exposition of chemical industries in the Grand Central Palace, New York City. Managers, Charles F. Roth and Fred W. Payne, Grand Central Palace, 46th St. and Lexington Ave., New York City.

December 7-13—National Exposition of Power and Mechanical Engineering at the Grand Central Palace, New York City. Charles F. Roth, manager, Grand Central Palace, 46th St., and Lexington Ave., New York.

SOCIETIES, SCHOOLS AND COLLEGES

University of Delaware, Newark, Del. Annual catalogue for 1921-1922, containing calendar, courses of study, and other related information.

Clarkson College of Technology, Potsdam, N. Y. Catalogue for 1922, containing calendar for 1921-1922, courses of study, and other information relative to the college.

Polytechnic Institute of Brooklyn, Brooklyn, N. Y. Catalogue of the College of Engineering for 1922-1923, containing calendar, requirements for admission, description of courses, and schedules for both day and evening departments.

Ohio State University, Columbus, Ohio. Educational Research Bulletin No. 9, containing announcement of summer quarter courses offered in the College of Education, the first term of which begins on June 19 and the second on July 27.

NEW BOOKS AND PAMPHLETS

Cutting Fluids. By Eugene C. Bingham. 76 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Technologic Paper No. 204 of the Bureau of Standards. Price, 15 cents.

An Investigation of the Properties of Chilled Iron Car Wheels. By J. M. Snodgrass and F. H. Guldner. 103 pages, 6 by 9 inches. Published by the Engineering Experiment Station of the University of Illinois, Urbana, Ill., as Bulletin No. 129.

Tensile Properties of Some Structural Alloy Steels at High Temperatures. By H. J. French. 92 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Technologic Paper No. 205 of the Bureau of Standards. Price, 5 cents.

Some Effects of the Distributed Capacity between Inductance Coils and the Ground. By Gregory Breit. 7 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Scientific Paper No. 427 of the Bureau of Standards. Price, 5 cents.

Manufacture and Properties of Steel Plates Containing Zirconium and other Elements. By George K. Burgess and Raymond W. Woodward. 54 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Technologic Paper No. 207 of the Bureau of Standards. Price, 20 cents.

Report of the Engineering Foundation for the Year Ended February 9, 1922. 92 pages, 7 by 10 inches. Published by the Engineering Foundation, Engineering Societies Building, 29 W. 39th St., New York City, as Publication No. 4.

In addition to the report for the year contained in this publication, there is also a report of a research on the fatigue of metals, which is given in full, including diagrams and tables.

Construction of Radiophone and Telegraph Receivers for Beginners. By M. B. Sleeper. 142 pages, 5¼ by 7½ inches. Published by the Norman W. Henley Publishing Co., 2 W. 45th St., New York City. Price, 75 cents.

The widespread interest in wireless telephony has created a demand for books on this subject, especially for those containing instructions for amateurs who are building their own equipment. This book which is written for the beginner, gives directions for the construction of radiophone and telegraph receivers. Special receivers, both crystal and audion, are shown in detail. The material is illustrated by halftones, diagrams, and working drawings, which have been especially prepared for this book. The information covers the erection of antennas, planning a station, and building all kinds of crystal, audion and regenerative receivers, with amplifiers and "loud speakers" for receiving radio telephone broadcasting and telegraph signals.

The Iron Man in Industry. By Arthur Pound. 230 pages, 5½ by 8 inches. Published by the Atlantic Monthly Press, 8 Arlington St., Boston, Mass. Price, $1.75.

This is an interesting contribution to the literature on industrial problems. It points out the social significance of the automatic machine, which the author calls the "iron man," and the labor problems that have followed in its wake. The author has worked in factory towns at a trade, and has been both employer and employe, reporter, editor, and printer, so that he has had an opportunity to look at the problem of social unrest from more than one point of view. He begins his book with a study of industrial and social conditions in Flint, Mich., showing the effect of the automatic machine in the manufacturing center of the automobile industry. He then goes on to consider the problem in its national aspects. He points out the need for adapting present-day education to the march of civilization exemplified in the use of automatic machinery, and makes a plea for a better use of the leisure which the "iron man" has brought to the world.

Human Factors in Industry. By Harry Tipper. 280 pages, 5 by 7½ inches. Published by the Ronald Press Co., 20 Vesey St., New York City. Price, $2.

This book contains an analysis of the present situation relating to capital and labor and discusses many of the experiments that are being made with a view to obtaining better industrial conditions. The first part of the book contains an outline of the history of labor unions for the past century and discusses their present tendencies and prospects. Manufacturers' associations and the influence on modern industrial problems of recent developments in industrial, economic and political theory are also considered. Particular attention is given to the influence of the modern tendency toward specialization. The second part of the book treats of various remedial changes which are being tried, discusses incentives in industry, the wage system, bonuses and profit-sharing, the employment and industrial relations departments, employe representation, and the open shop issue. The book is the result of many years of intimate observation by the author in actual work with labor and in supervising all kinds of labor.

Metal Cutting Tools. By A. L. DeLeeuw. 328 pages, 6 by 9 inches. Published by the McGraw-Hill Book Co., Inc., New York City. Price, $3.

The object of this book is to set forth the principles which must be applied in the selection, design, maintenance and use of metal-cutting tools. It is primarily intended for the young engineer, student, foreman, time-setter, and particularly for the ambitious mechanic who is desirous of basing his skill on knowledge. The principles underlying the cutting action of metal-cutting tools are not yet absolutely established, but the material presented is based on numerous observations of the author and others. There are eighteen chapters dealing with the following subjects: Formation of Chips—Elementary Considerations in the Construction of Simple Tools; Consideration of the Element of Feed—Analysis of the Round-nosed Tool—Effect of Fundamentals of Cutting on Design; Various Types of Planer Tools; Standard Lathe Tools and Boring Mill Tools; Boring Tools; Single and Multiple Boring Tools—Reamers; Milling Cutters—Gear Cutters and Hobs; Cutter Sharpening; Form Tools; Shear Tools; the Use of Liquids when Cutting Metals; Generating Tools; Thread-cutting Tools; Hollow Mills, and Special Tools.

American Travel and Hotel Directory. 2008 pages, 6 by 9 inches; numerous illustrations. Published by the American Travel and Hotel Directory Co., Inc., Baltimore, Md. Sold by The Industrial Press, 140-148 Lafayette St., New York City. Price $10.

The 1922 edition of this well-known directory contains a vast amount of information of great value to everyone who travels for business purposes. It contains a complete list of all hotels in the United States, indicating the class of hotel, rates, etc., and also gives the same information for hotels in Canada and Latin America. In addition, it contains tables giving railroad fares and Pullman berth rates between the principal cities in the United States. The arrangement of the information in the book is very convenient. All states are arranged alphabetically, and under each state the cities and towns are also arranged in alphabetical order. A general description of the various states and cities, particularly from an industrial point of view, is given in this connection, and a list of local holidays for each state is included. This is a book that, when properly consulted and used, will easily save its cost several times over in the office of any firm or corporation that has sales and traveling men needing exact information, carefully condensed and classified. It makes it possible to reserve accommodations in advance at stated rates, and to plan business trips intelligently beforehand. In addition to the hotel directory, there is a brief description in connection with each city giving altitude, population, location, transportation facilities, telegraph, banking and express facilities, etc., and an outline of the principal industries.

NEW CATALOGUES AND CIRCULARS

Goddard & Goddard Co., Detroit, Mich. Folder entitled "A Statement," relating to the development of curved-back tooth milling cutters, as made by the company.

Kurtz Equipment Co., 57 W. Houston St., New York City. Circular advertising Kurtz trucks, casters, barrel racks, tiering machines, and other indoor handling equipment.

Heine Boiler Co., (formerly Heine Safety Boiler Co.), St. Louis, Mo. Pamphlet entitled "Forty Years of Progress," announcing a change in name and several new developments in boiler design.

R. S. Whitney Mfg. Co., 74 Nichols St., Lewiston, Me. Circulars illustrating and describing Whitney standard garage equipment, including arbor presses, automobile jacks, etc., and Whitney valve refacing lathe.

Griscom-Russell Co., 90 West St., New York City. Bulletin 360, describing the application of evaporators to the purification of boiler feed water by distillation, and illustrating the Reilly self-scaling evaporator.

Van Dorn & Dutton Co., Cleveland, Ohio. Leaflet treating of Van Dorn gears, containing information relative to the materials used and illustrations showing views in the gear-cutting and heat-treating departments.

Spencer Lens Co., Buffalo, N. Y. Catalogue covering the Spencer products for commercial and industrial laboratories, which include projection apparatus, microscopes, photo-micrographic cameras, colorimeters, spectroscopes, photographic lenses, etc.

Nice Ball Bearing Co., Nicetown, Philadelphia, Pa. Catalogue giving dimensions and list prices of Nice annular type ball bearings, thrust bearings, and combination radial and thrust load ball bearings. Prices are also given for ball retainers and ball-bearing wheels.

Ingersoll-Rand Co., 11 Broadway, New York City. Bulletin 10004, descriptive of Type PO horizontal single-cylinder four-stroke cycle stationary oil engines. The features of construction are described in detail and data are given on fuel consumption, dimensions, etc.

N. A. Strand & Co., 625 W. Jackson Blvd., Chicago, Ill. Catalogue 22, covering the line of flexible shafts and equipment made by this concern. The equipment is applicable for grinding, polishing, sanding, drilling, reaming, tapping, tire-buffing, nut-setting, screw-driving, and many other operations.

Armstrong-Blum Mfg. Co., 343 N. Francisco Ave., Chicago, Ill. Catalogue 5, illustrating and describing the line of "Marvel" machines made by this concern, which includes high-speed sawing machines, hacksaws, band saws, punches and shears, drill press vises and combination punching, shearing, and bending machines.

Kearney & Trecker Corporation, Milwaukee, Wis. Circular illustrating Milwaukee milling machines and giving data on the saving in production costs effected in milling transmission cases, connecting-rods, cylinder blocks, and clutch adjusting rings, by the use of special attachments and fixtures designed for these machines.

Tide Water Oil Sales Corporation, 11 Broadway, New York City. Catalogue entitled "One Hundred and One Economies for the Motorist," containing information on the proper lubrication of all the different parts of automobiles. A diagram of a car is presented, on which is shown the location of every part that requires lubrication.

James Clark, Jr., Electric Co., Inc., Louisville, Ky., is issuing a monthly publication for the benefit of its selling agents and salesmen, known as the "Jaco Driller" which contains news relating to the activities and personnel of the firm, and information concerning its product, which comprises portable electric drills and other electrically driven tools.

Rochester Electric Products Corporation, Rochester, N. Y., has just issued the first of a series of pamphlets entitled "Little Motor Talks." Pamphlet 1 takes up the subject of brush mounting, and other features of motor design will be dealt with in subsequent issues. The company will be glad to place those interested in motors on its mailing list for the entire series.

Nilson-Miller Co., 1300 Hudson St., Hoboken, N. J. Card containing information on the gear-cutting service which this company is in a position to render, including the cutting of spur gears up to 66 inches in diameter, bevel gears up to 24 inches in diameter, helical gears up to 18 inches in diameter, internal gears up to 30 inches in diameter and worm-gear sprockets, intermittent gears, etc.

W. S. Rockwell Co., 50 Church St., New York City. Circular illustrating and describing Rockwell stationary and tilting crucible melting furnaces for aluminum, brass, bronze, copper, gold, monel metal, nickel, silver, and other non-ferrous

metals. These furnaces are operated with either oil or gas fuel. Dimensions are given covering the three sizes of stationary furnaces and the four sizes of tilting furnaces.

Turner Brass Works, Sycamore, Ill. Circular listing the principal points of construction in the Turner "Master" line of blow-torches, which may be used for burning either gasoline or kerosene. Particular attention has been given to safety features in the design of these torches. This line is an addition to the regular line of blow-torches made by this concern. List prices are given for the different sizes.

Scovell, Wellington & Co., Boston 9, Mass., accountants and engineers, have compiled a list of four hundred books on accountancy, industrial engineering, and related business topics. This list was prepared originally for the use of members of the company and clients, but is now being distributed without charge to those interested in buying business books on these subjects for their own use or for a commercial library.

Grindle Fuel Equipment Co., Harvey, Ill. General catalogue of Grindle powdered fuel equipment, pointing out the advantages of powdered fuel and the special features of the Grindle system. The catalogue contains many illustrations showing the Grindle powdered coal system, multiple-tube dryer, pneumatic conveying system, firing equipment, storage hoppers and tanks, etc. copies will be sent to those interested upon request.

General Tool & Equipment Co., 70 Monroe St., Chicago, Ill. Circular descriptive of the Sapihl portable electric grinder, which is especially adapted to valve grinding. The illustrations show some of the various uses of this tool in automobile shops and machine shops, for valve grinding, reamer and tool sharpening, surfacing, internal grinding, toolpost grinding, cotter grinding, and die work. Complete specifications for the tool are given.

Ingersoll Milling Machine Co., Rockford, Ill. Circular illustrating the use of the Ingersoll adjustable rotary milling machine in railroad shops for profile-milling such as, for example, milling the radius on the end of main rods, milling steel straps, side-rods, etc. The combination of the movements to the head, housing, table saddle and rotary table give the machine a wide range. Complete data for the various operations are given.

Newark Gear Cutting Machine Co., Newark, N. J. Catalogue 3, containing a detailed description of Newark spur gear cutting machines. The general description is followed by illustrations of the different types of machines and complete specifications, the specifications for each machine being given on the page opposite the illustration. The book concludes with tabular matter, relating to sizes and prices of involute gear cutters, instructions for sizing and cutting gears, and data on tooth parts.

W. J. Savage Co., Inc., Knoxville, Tenn. Circulars containing illustrations, descriptive material, and specifications covering the line of sheet-metal cutters made by this concern. These machines are made in four sizes—Nos. 0, 1, 2, and 3 for cutting stock up to 1/8, 3/16, 3/8, and 5/8 inch thick respectively. They are so designed that they will cut any shape out of sheets or plates and will finish inside angles, corners, or curves, in the same operation, thus eliminating torch-cutting, drilling, and hand work.

Condensite Co. of America, Bloomfield, N. J. Catalogue telling what condensite is and the many uses for which it is adapted. The illustrations show a variety of products made from this material. Catalogue entitled "Condensite in the Automotive Industry" showing the application of condensite to this particular field. On alternate pages are shown photographs of automobile parts made from this material, and on the opposite pages are brief statements pointing out the advantage of condensite for the parts shown.

Charles H. Besly & Co., 120-B N. Clinton St., Chicago, Ill. General catalogue of Besly grinding machines containing complete specifications and illustrations of the disk and ring-wheel single- and double-spindle grinders. These machines are of the ring-oiling type, and the construction of the ring-oiling spindle is illustrated and described in detail. All the single-spindle machines may be arranged for motor drive. Circular descriptive of the Besly "Titan Non-glaze" abrasive disks, which are made for use on Besly grinding machines.

Boston Gear Works, Norfolk Downs, Quincy, Mass. 1922 edition of general catalogue No. 40, covering 600,000 standardized Boston gears carried in stock in 1500 sizes. The latest addition of steel and iron internal gears for use with the company's new style pinions of less than twelve teeth are shown on pages 64 to 71. Complete data including dimensions, prices, etc., are given for brass, iron and steel bevel and spur gears, worm-gears, sprockets, etc. The catalogue also gives dimensions and prices of universal joints, ball bearings and thrust washers.

TRADE NOTES

J. Horstmann, dealer in machinery, tools, and steels, 81 Rue St. Maur, Paris, France, discontinued its New York office on May 15.

Acme Stamping & Machine Co., has reincorporated, and has changed its name to Acme Stamping & Mfg. Co. The firm is now located at 119 Sheldon St., Chicago, Ill.

Metal & Thermit Corporation, 120 Broadway, New York City, has removed its Pittsburg branch office from 1427 Western Ave. to 801 Hillsboro St., Corliss Station.

Alvord Reamer & Tool Co., Millersburg, Pa., manufacturer of reamers, milling cutters, twist drills, drop-forgings, punches and dies, and special tools, has moved its Philadelphia office to 228 Church St.

Reeves Pulley Co., Columbus, Ind., announces that the manufacture and sale of the Reeves centerless roll grinder will be carried on in the future from the office and factory of the company at Columbus, instead of through a sales agency as heretofore.

Sharon Pressed Steel Co., New York City, has moved its office from 66 Broadway to the company's new warehouse in the Dodge building, 47 West Broadway, corner of Murray St., where a complete line of trucks, trailers, skids, and other pressed steel products will be carried.

Arthur M. Watkins, dealer in machine tools, eastern agent for the Covington Machine Co., and New York agent for the American Tool Works Co.'s planers and the Ohio Machine Tool Co.'s shapers, has moved his offices from 165 Broadway to the Dodge Building, 53 Park Place, New York City.

General Tool & Equipment Co., 70 Monroe St., Chicago, Ill., has been appointed exclusive selling agent for the portable electric grinder made by the Sapihl Electric Tool Co., of Galesburg, Ill., in the states of Michigan, Ohio, Kentucky, Minnesota, North and South Dakota, Iowa, Indiana, Illinois and Pennsylvania.

Bristol Co., Waterbury, Conn., manufacturer of recording instruments, has opened a branch office at Philadelphia, in the Widener Bldg., Room 1311. C. C. Eagle, Jr., is in charge of the new office. Mr. Eagle has had wide experience, including laboratory training at the factory and sales training in the field. He was formerly in charge of the Detroit office.

Reeve-Fritts Co., 37 S. DesPlaines St., Chicago, Ill., has been formed for the purpose of dealing in new and second-hand machine tools. The officers of the company are J. E. Fritts, president and treasurer, and H. J. Reeve, vice-president and secretary. Both Mr. Fritts and Mr. Reeve were formerly associated with the Stocker-Rumely-Wachs Co. of Chicago.

Westinghouse Electric & Mfg. Co., East Pittsburg, Pa., has recently erected a new building in Huntington, W. Va., at Second Ave. and Ninth St. The building is a three-story structure containing 30,000 square feet of floor space. The activities of the sales, service, and warehouse departments have been coordinated in the new building, and this, together with the better facilities provided, is expected to result in more effective service to customers.

Herberts Machinery & Supply Co., corner of Third and San Pedro Sts., Los Angeles, and 140 First St., San Francisco, Cal., dealer in machine tools and woodworking machinery, has been appointed exclusive representative for California, Arizona and Nevada for the Norton line of grinding machines, built by the Norton Co., Worcester, Mass. The Herberts Machinery & Supply Co. has placed an order for two carloads of grinding machines with the Norton Co. for stock purposes, which will enable them to take care of their trade by giving immediate delivery.

Oneonta Iron Works, Inc., Oneonta, N. Y., have recently opened the foundry previously operated by the Titchener Colver Iron Works, and will do a general jobbing business. A cupola with a capacity of from 6 to 7 tons has been installed. The officers of the concern are as follows: President, F. G. Schifferdecker; vice-president and general manager, R. S. Findlay. Mr. Findlay has been general foreman of the Hudson Coal Co.'s repair shops at Scranton, Pa., for the last four years, and previous to that time was engaged for a number of years on river harbor improvements for the United States Government.

Dodge Sales & Engineering Co., Mishawaka, Ind., manufacturer of power transmission appliances and heavy oil engines, has removed its New York City branch from 21 Murray St., to the Dodge Building at 53 Park Place, New York City. The new Dodge building is twelve stories high and is of steel and concrete construction. This company has maintained a branch and warehouse in New York City for over twenty-eight years, and in moving to its new location, which is convenient to shipping and railway facilities, will be in a position to handle more efficiently its local and export business.

Modern Machine Tool Co., Jackson, Mich., has taken over from the Sprague-Hayes Mfg. Co., of Detroit, Mich., the manufacture of a special combination table and vise for use on drilling machines. This device will now be manufactured by the Modern Machine Tool Co. on a royalty basis, under license from the inventor, George H. Cocks of Adrian, Mich. With the manufacturing rights, the Modern Machine Tool Co. acquired the tools, patterns, jigs, fixtures, etc., and also the stock of raw materials and finished table-vises which the Sprague-Hayes Mfg. Co. had on hand.

Arrow Tool & Mfg. Co., 200 Cannon St., Bridgeport Conn., has changed its name to the Forsberg Mfg. Co. This change was made because another company, which has been in business for a longer period of time, uses the word "Arrow" in its name and trademark. The Forsberg Mfg. Co. will continue to make tools and special machinery of all kinds. An up-to-date press room has been added to the plant, and the company is prepared to make stampings and sheet-metal specialties of steel, brass, aluminum, or other metals, in large quantities. In addition it is making a complete line of hacksaw frames. No change will be made either in the ownership or management.

General Electric Co., Syracuse, N. Y., announces a number of important changes in the directorate of the company: C. A. Coffin has retired as chairman of the board of directors and has been succeeded by Owen D. Young, who has been a vice-president of the company for many years. Gerard Swope, president of the International General Electric Co., has been elected president, succeeding E. W. Rice, Jr., who will devote his entire energy to the further upbuilding of the scientific, engineering, and technical phases of the company's work, and who will become honorary chairman of the board of directors. Anson W. Burchard, for many years vice-president of the company in charge of public utilities and foreign investment, was elected vice-chairman of the board. J. R. Lovejoy and G. F. Morrison were elected directors.

STATEMENT OF THE OWNERSHIP, MANAGEMENT, ETC., REQUIRED BY THE ACT OF CONGRESS OF AUGUST 24, 1912

of MACHINERY, published monthly at New York, N. Y., for April 1, 1922.

State of New York } ss.
County of New York }

Before me, a Notary Public in and for the state and county aforesaid, personally appeared Matthew J. O'Neill, who, having been duly sworn according to law, deposes and says that he is the treasurer and general manager of the Industrial Press, Publishers of MACHINERY, and that the following is, to the best of his knowledge and belief, a true statement of the ownership, management, etc., of the aforesaid publication for the date shown in the above caption, required by the act of August 24, 1912, embodied in section 443, Postal Laws and Regulations, printed on the reverse of this form, to wit:

1. That the names and addresses of the publisher, editor, managing editor, and business managers are: Publisher, The Industrial Press, 140-148 Lafayette St., New York; Editor, Erik Oberg, 140-148 Lafayette St., New York; Managing Editor, None; Business Managers, Alexander Luchars, President, 140-148 Lafayette St., New York, and Matthew J. O'Neill, Treasurer and General Manager, 140-148 Lafayette St., New York.

2. That the owners of 1 per cent or more of the total amount of stock are: The Industrial Press; Alexander Luchars; Alexander Luchars, Trustee for Helen L. Ketchum, Elizabeth Y. Urban, and Robert B. Luchars; Matthew J. O'Neill; Louis Pelletier; and Erik Oberg. The address of all the foregoing is 140-148 Lafayette St., New York.

3. That there are no bondholders, mortgagees, or other security holders.

4. That the two paragraphs next above, giving the names of the owners, stockholders, and security holders, if any, contain not only the list of stockholders and security holders as they appear upon the books of the company but also, in cases where the stockholder or security holder appears upon the books of the company as trustee or in any other fiduciary relation, the name of the person or corporation for whom such trustee is acting is given; also that the said two paragraphs contain statements embracing affiant's full knowledge and belief as to the circumstances and conditions under which stockholders and security holders who do not appear upon the books of the company as trustees, hold stock and securities in a capacity other than that of a bona fide owner; and this affiant has no reason to believe that any other person, association, or corporation has any interest direct or indirect in the said stock, bonds, or other securities than as so stated by him.

MATTHEW J. O'NEILL, General Manager

Sworn to and subscribed before me this 17th day of March, 1922.

(SEAL)

WILLIAM E. BACON,
Notary Public, Kings County No. 444
Kings Register No. 8109
New York County No. 79 New York Register No. 8047
(My commission expires March 30, 1923.)

MACHINERY

JULY, 1922

VOL. 28 NO. 11

Approved Methods of Grinding Such Important Parts as Pistons, Piston-rings, Piston-pins, Cylinders, Connecting-rods, Crankshafts, Camshafts, Gear Teeth and Spline Shafts

First Installment of a Series of Five Articles on Grinding in Different Industries, by the Engineering and Educational Departments of the Norton Company, of Worcester, Mass.

Grinding in the Automotive Industry

THE automotive and allied industries, including the manufacture of automobiles, motorcycles, trucks, airplanes, tractors, ball and roller bearings, universal joints, and transmissions, consume more grinding wheels than all other industries combined. In the automotive industry, interchangeable manufacture is of particular importance, and as small tolerances are allowed for most of the parts, grinding is the only economical method of producing them. Another reason for the extensive application of grinding in this field is that a large number of hardened steel parts are used. Hardened work can be machined commercially only by grinding. Almost every part is ground at some stage of its manufacture, and in many cases grinding is by far the most important operation.

There are many automotive parts that are simple cylindrical pieces ground on the ordinary type of cylindrical grinding machine, there being nothing unusual about the operation. This class includes such parts as push-rods, pump shafts, shackle bolts, pins, and bushings. Bushings are also ground internally on standard internal grinding machines, the operation being simple and not of special interest. There are, however, many grinding operations that are characteristic of the automotive industry, and that represent interesting examples of grinding practice, and these will be dealt with in this and in a second article to appear in August MACHINERY.

Fig. 1. Cylindrical Grinding Operation on Pistons

Pistons, such as are used in the automotive industry, are made from either cast iron or aluminum. The grinding of cast-iron pistons will be considered first. The important operation is cylindrical grinding (see Fig. 1). This follows a rough-turning operation in which the castings are turned to within about 0.025 inch of the finished size. The piston is held on a special fixture, which makes it possible to grind the entire length with one set-up of the machine. Three types of these special fixtures are illustrated in Fig. 2. The construction will be readily understood by referring to this illustration in connection with the description.

The grinding fixture shown at *A* has a conical-shaped part (made of cast iron), which is mounted on the hardened taper bearing of a dead center, and is revolved by the faceplate driving pin. This conical casting carries three equally spaced jaws which may be adjusted along dovetail slots to suit the diameter of the piston that is to be ground. Each jaw is split lengthwise, and has a taper screw which spreads it in the slot for locking in any position. A notch in each jaw provides clearance for the grinding wheel, as the illustration shows. The dead center which supports the conical-shaped chuck is inserted in the main spindle of the grinding machine.

The fixture shown at *B* is very simple; it consists of a steel disk-shaped part for supporting the open end of the piston, with a driving pin that engages one of the wrist-pin bosses, and another pin that engages the driving pin on the machine faceplate. In this case, as in the preceding one, the regular machine center is used for supporting the outer end of the piston.

A third design of fixture is shown at *C*. A loose pin is inserted in the wrist-pin holes so that it extends across the piston and through an elongated hole in the central arbor. After the back-plate is placed in the open end of the piston, the taper drift key is driven in, thus holding the parts firmly together. This simple method of holding a piston has proved very effective.

In grinding pistons, the "draw-in-cut" method is generally combined with the stroke method; that is, the wheel is fed in at one end to within 0.001 or 0.002 inch of the finished size, traversed once by hand the entire length of the piston, and then automatically traversed until the diameter is correct. Usually only one automatic traverse is needed, although in some cases several complete passes may be necessary.

Wheels Used for Piston Grinding

When the "draw-in-cut" method is used, the corner of the wheel removes practically all of the stock, and must therefore wear very slowly. This makes it necessary to use harder wheels than when the stroke method is used for the complete operation, as in the latter case the feed for each traverse is only 0.001 or 0.002 inch. Silicon carbide wheels of medium grade are in use in shops where the "draw-in-cut" method is followed, while in the case of the stroke method, wheels in the soft range are more common.

In many plants, roughing is done on one machine and finishing on another, two different grains and grades of wheels being used. In other plants, the piston is ground to the finish desired in one operation, in which case the corner of a hard wheel does the cutting, and the remainder of the face, being glazed, burnishes the surface of the work. The production is often as high as one piston per minute.

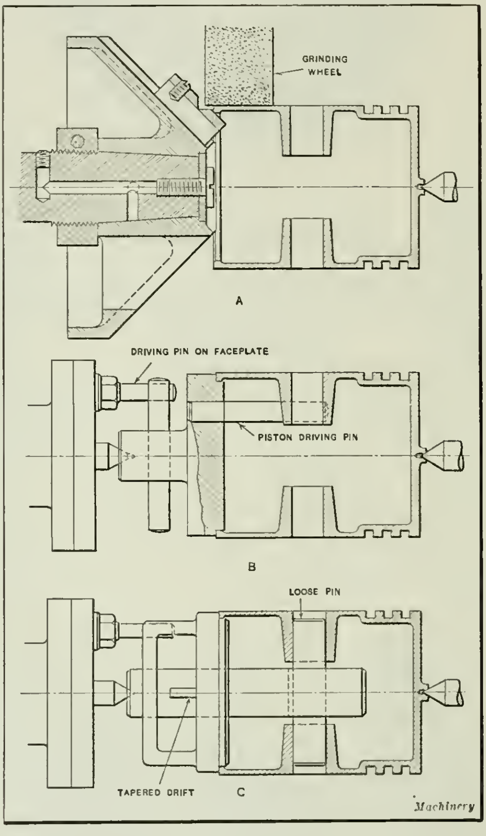

Fig. 2. Three Types of Fixtures or Arbors for holding Pistons while grinding

More care must be exercised when grinding aluminum than when grinding cast-iron pistons. Both aluminous and silicon carbide abrasive wheels are used for this work.

[Note: The silicon carbide abrasives represented by crystolon, carborundum, etc., differ materially from the aluminous abrasives such as alundum, aloxite, etc. The grains of the former are harder but are also more brittle due to the structure; the grains of the latter, while not as hard, are tougher and do not break apart as easily, thus being able to withstand a greater stress. In addition, the aluminous abrasives admit of a certain range of toughness in their manufacture. On account of the difference in physical characteristics of the two abrasives, a general rule has been established, namely, that aluminous abrasives are used for grinding materials of high tensile strength, and silicon carbide abrasives for those of lower tensile strength. While tensile strength alone is not the criterion, inasmuch as hardness and ductility influence the selection, experience has shown that, in general, the aluminous abrasives are particularly adapted for grinding materials of high tensile strength.]

It is very difficult to grind aluminum without producing scratches, unless the operator is very expert, because either a loaded wheel, or abrasive particles coming between the wheel and the piston result in objectionable scratches. The first difficulty is reduced to a minimum, or even obviated entirely, by using a wheel which breaks down easily, as, for instance, an aluminous abrasive elastic wheel, or by treating the wheel face in such a way that the metal particles cannot be forced into the voids between the grains. In the latter case, if silicon carbide vitrified wheels are used, beeswax or paraffin is often rubbed into the wheel face, which, in addition to reducing the loading tendency, helps to give the polished finish commonly desired. High work speeds and frequent truing with a diamond are helpful in reducing the loading.

To prevent the abrasive particles from flowing between the wheel and the piston, the tank should be kept clean and the lubricant renewed frequently. Often a fine-mesh cloth screen is attached to the tank end of the lubricant pipe. The common lubricants used on other grinding work do not give the best results on aluminum. Kerosene or a mixture of kerosene and lard oil are most commonly used.

In addition to the periphery, two other parts of the piston (whether made of cast iron or aluminum) are sometimes ground, namely, the relief around the pin-hole and also the top. For grinding around the pin-hole, the piston is held off center in a cylindrical grinding machine and the relief ground with a narrow wheel. Some manufacturers finish the top of the piston very carefully, because of the belief that any irregularity tends to facilitate the deposit of carbon. This work may be done (1) on a Blanchard type of grinding machine, (2) on a rotary surface grinding machine of the Heald type, or (3) on a disk grinding machine equipped with abrasive disks mounted on metal plates.

Piston-ring Grinding

Piston-rings are finished almost entirely by grinding. Castings are made either singly or in cylinder form, the latter being cast by the "pot" method. When single cast rings are used, the rough rings, as they come from the foundry, must be snagged in order to remove the sprues and fins. Silicon carbide wheels are preferable for this work. Following this operation the rings are either rough-ground cylindrically, being held in a fixture and rotated against the grinding wheel by hand, or are rough-turned. They are then rough-surfaced in any one of several different ways, the most common method being to use a rotary type of surface grinding machine. Abrasive disks and cylinder wheels are also used for this work in a few plants, the latter method being the more commonly used of the two.

A special type of machine for surface-grinding piston-rings has two cylinder wheels mounted with their faces close together, the distance between them being equal to the desired thickness of the rough-ground ring. The rings are held in a suitable fixture and pushed between the two wheels. Usually about 0.003 inch of stock is left on the ring for the finish-grinding operation. Production of the common types of rings is about 200 rings per hour on this machine.

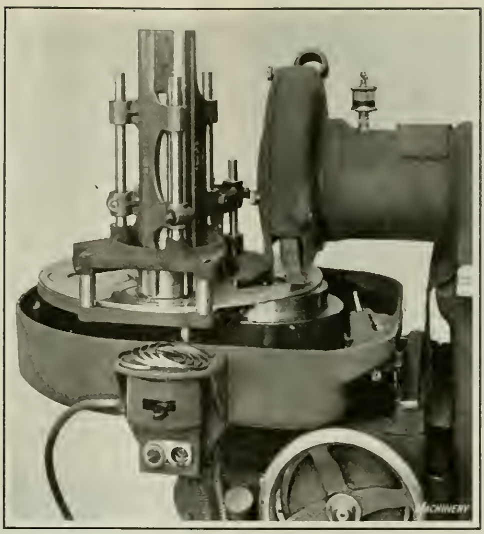

Fig. 3. Automatic Ring-grinding Machine

The finish surface grinding is always done on a rotary type of machine. This is one of the few grinding operations that can be done automatically. The Heald automatic ring grinding machine, shown in Fig. 3, has a magazine type of ring-feeding attachment, and is fully automatic. A feeding plate or carrier disk transfers the rings from the magazine to the grinding position. This disk has five holes to receive the rings, which may be bushed to take rings up to 5 inches in diameter. When the disk indexes, a ring is transferred from the magazine to the center of the magnetic chuck and then, after being ground, this ring is removed as another one slides around to the grinding position.

Current for the chuck is supplied through a rotating disk having an electrical contact. This disk is so timed with reference to the grinding operation that magnetizing the chuck to hold the ring for grinding, and demagnetizing both chuck and work to permit removal of the ground rings are automatically controlled. The wheel-slide of this machine is operated hydraulically, oil being used. A production of 1000 rings per hour may readily be attained.

Another type of attachment makes the surface grinding machine semi-automatic. In this case it is necessary for the operator to place the rings in the holder with one hand, and to remove the ground rings with the other hand, using a non-magnetic hook.

An interesting point in connection with the surfacing of piston-rings on the rotary type of surface grinding machine is the fact that aluminous instead of silicon carbide abrasive wheels are used. This practice is contrary to the general rule that materials of low tensile strength are best ground by silicon carbide wheels, and is probably followed because of the dressing action of the sharp corners of the rings, which makes it necessary to use a tougher abrasive in order to prevent excessive wheel wear.

After the surfacing operation, the rings are split and compressed to the required size, mounted in "gangs" on a special arbor and ground in a plain cylindrical grinding machine. This is merely an ordinary cylindrical grinding operation. Single cast rings are also ground internally, in some cases on a precision machine, but more frequently they are ground "off-hand," as it is not necessary to have the inside dimensions exact.

When rings are cast by the pot method, the castings are trued, bored, and then cut off into individual rings. As their thickness can be brought to size very accurately, only about 0.005 inch of stock being left for grinding, it is not necessary to rough surface-grind the rings. In this way one of the grinding operations which is necessary on single cast rings is eliminated. The other operations performed on rings that are cast by the pot method are exactly the same as in the manufacture of the single cast rings.

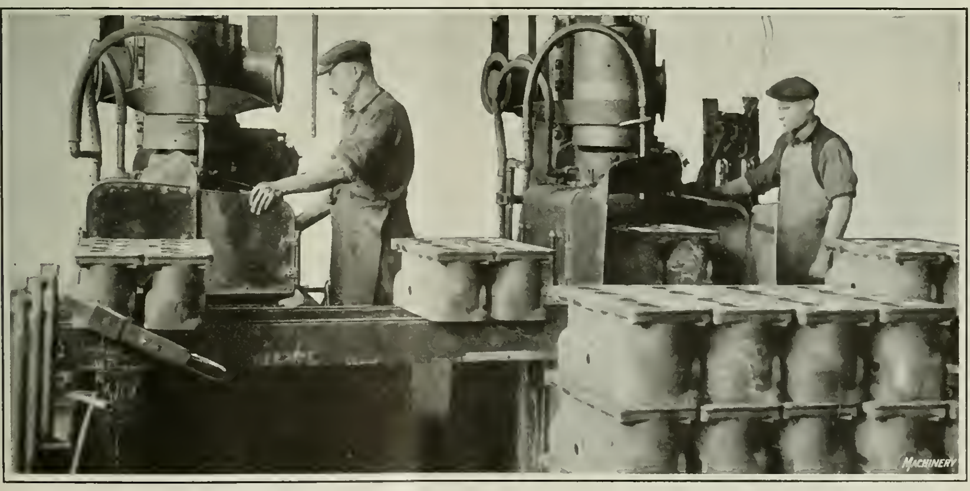

Fig. 4. Surface-grinding Operation on Cylinder Castings

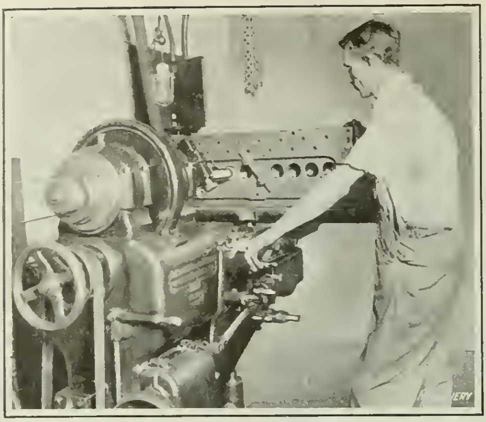

Fig. 5. Grinding Cylinder Bores

Piston-pins are plain cylindrical parts, but in spite of this, they are very difficult to manufacture. This is due to the fact that the pins are hollow, the walls being only about ⅛ inch thick, and also to the fact that in their manufacture they are usually held to the very close limit of from 0.0005 to 0.0002 inch. On this account great care must be exercised in order to produce perfectly cylindrical and uniformly hardened pins. The pins are formed on automatic screw machines, and after heat-treatment are ready for grinding.

Piston-pin Grinding on Cylindrical and Centerless Grinders

The grinding method used, whether it employs a narrow wheel with provision for traverse or a wheel slightly wider than the piston-pin, depends upon the practice of the individual shop. Two distinctly different types of cylindrical grinding machines are used. The older type is the plain cylindrical machine, in which the pins are mounted on arbors and ground like any cylindrical part of similar dimensions. If a wide wheel is used it is fed straight in, there being no traverse except for a slight hand movement of the table when the pin is ground nearly to the finished size. This slight traverse merely brings about somewhat of a dressing action, which helps to keep the wheel face straight. Grinding is done wet, and aluminous abrasive wheels are used which are usually of grain No. 36 combination or No. 46.

The newer type of machine used for this work is known as the "centerless" grinding machine. In the latest types of these machines, the work is held between the grinding wheel, a drive wheel, which is also an abrasive wheel, and a work shoe. The pieces to be ground are fed in at one side of the machine and the drive wheel, which is set at an angle, pulls the work past the grinding wheel. The greater the angle between the axis of the drive wheel spindle and that of the grinding wheel spindle, the faster the work travels. Grinding is done wet, and aluminous abrasive wheels are used. They must be finer than those used on the plain cylindrical grinding machine, and are usually of grain No. 46 or 60 for roughing and of grain No. 80 to 120 for finishing. With the first centerless machines it was difficult to produce round pins, but marked improvement has been made, although the quality is still inferior to that of pins ground on centers.

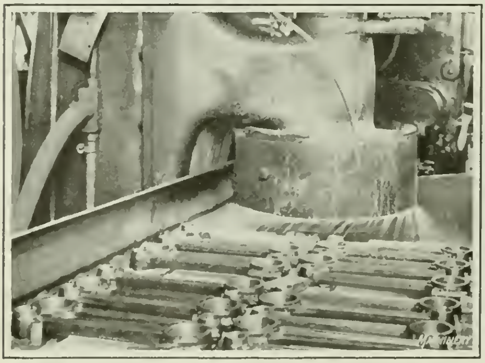

Fig. 6. Grinding the Side Faces of Connecting-rods

Surfacing Cylinder Castings

Cylinder castings are made of either cast iron or semisteel. The larger number at present are made of semisteel, which consists of about 20 per cent steel scrap added to the cast iron. This metal must be considered of low tensile strength, and it is most efficiently ground with silicon carbide wheels, the same as cast iron. The important result of adding the steel scrap is to refine the iron and make it finer grained, rather than to increase the tensile strength to a point where it would approach that of soft steel.

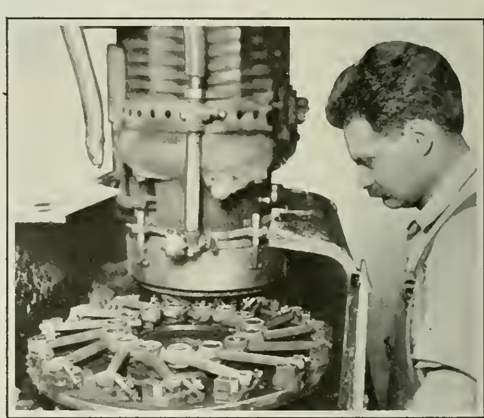

Fig. 7. Another Method of grinding the Side Faces of Connecting-rods

Cylinder castings are surfaced-ground, on a machine of the Blanchard, Pratt & Whitney, or Diamond type, for the purpose of making a commercially perfect joint with the crankcase and also (if the casting is of the open-head type) with the cylinder head. Fig. 4 shows Blanchard machines surface-grinding cylinder castings. The production secured by this operation, because of the rapid removal of stock, compares favorably with the results obtained by milling. The use of water in the grinding makes it possible to maintain high production.

Grinding Cylinder Bores

Before the development of the gasoline engine, cylinders such as are used in pumps and steam engines were usually machined by boring with a single-point tool, there being a sufficient amount of metal in the cylinder wall to resist the pressure exerted by the tool. The gasoline engine cylinder has such thin walls, however, that this method of boring would not give satisfactory results, because the walls would spring and the tool would slide over hard spots in the casting and gouge into soft spots, leaving an irregular surface. Grinding provides an accurate method of finishing cylinder bores, and most automobile engine cylinders are ground, although some manufacturers prefer reaming. (For a discussion of the two methods, see March, 1919, MACHINERY, page 615.) The eccentric-spindle type of cylinder grinding machine is used for automotive work.

Fig. 5 shows a Heald machine grinding the bores of an eight-cylinder engine. The grinding wheel is mounted on a spindle which, in addition to rotating about its own axis, also travels in a circular path concentric with the circumference of the cylinder hole, making it unnecessary to rotate the work. The cylinder casting is mounted on the machine table, which travels parallel with the axis of the grinding wheel spindle.

The holes are first rough-bored, leaving about 0.005 to 0.008 inch for grinding. This material can be removed easily in three complete passes of the work. The first two roughing cuts are made with the highest speed of table traverse and the lowest eccentric speed, and the finishing cut is made with the lowest table speed and highest eccentric speed. The production naturally depends upon the size of the hole and the amount of stock left for grinding. There are cases on record where as many as eighty holes were ground in an eight-hour day on a single grinding machine, the work being done at the rate of six minutes per hole.

Truing Wheel, Removing Chips, and Cooling Work

Before grinding a cylinder, the wheel must be carefully trued, which should always be done with a diamond. The corners should then be touched up with a silicon carbide abrasive stick or wheel stub, as the sharp corners sometimes

Fig. 8. Internal Grinding Operation on Large End of Connecting-rod

produce feed lines. It is possible in many cases to produce from twenty-five to thirty commercially finished cylinders after each truing, although if a very smooth surface is required, it may be necessary to true the wheel before finish-grinding each hole.

The grinding should always be done dry. Attempts have been made to cool the casting by letting water flow into the hole, but the cast-iron or semi-steel chips and grinding dust that collect at the bottom of the hole form a mud, into which the grinding wheel dips at each revolution of the eccentric. This mud fills up the wheel face and seriously impairs the cutting action. The dust and chips are preferably removed dry by a suction pipe placed at the end of the cylinder hole. This method has practically no cooling effect. A cool cutting wheel is therefore essential, although some of the heat can be carried away by letting water flow over the cylinder or through the water jacket or chambers. In some cases the holes are rough-ground and the casting set aside to cool before the final 0.001 or 0.002 inch of stock is removed. However, this method involves handling the castings twice, and is probably unnecessary, if care is used in cooling the casting as described.

Grinding Compared with Reaming

As a final finishing operation for cylinder holes, grinding is generally considered superior to reaming for the following reasons:

1. A fine finish can be obtained with a grinding wheel much more rapidly than with a reamer. While a good finish

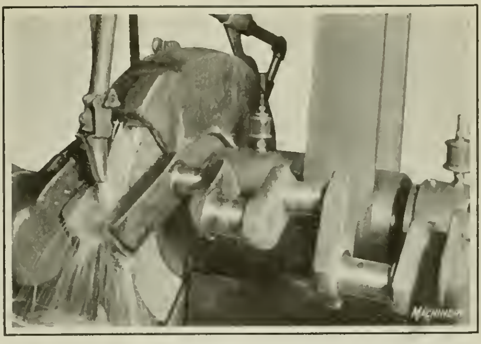

Fig. 9. Grinding Crankpins on a Double-head Type of Machine

may be obtained by taking very light cuts with the reamer, an excessive amount of time is consumed. Much depends, however, upon the reamer and the method of using it, and some automobile manufacturers contend that the finish obtained by a good reamer meets practical requirements, although most cylinders are ground, especially for cars of the better grade.

2. The hard and soft spots that frequently occur in a cylinder casting make it very difficult, and almost impossible in fact, to obtain an even, round hole with a steel tool. A grinding wheel grinds this hard material just as well as the soft sections.

3. There is a tendency for a steel tool to follow more or less the path of least resistance. If, therefore, the hole is not cored straight in the casting, it quite frequently happens that the bored and reamed hole is not at right angles to the crank end.

Grinding Operations on Connecting-rods

The grinding operations on connecting-rods are snagging, surface grinding, and internal grinding. The first operation is not of special interest; it consists merely of removing the stock rapidly by the use of a coarse, hard wheel. The bearing cap and connecting-rod, where they fit together, may be ground to a plane surface and accurate fit by the rim of a small cup-wheel. The side faces of the rods are surface-ground on a Pratt & Whitney or Blanchard type of vertical-spindle surface grinding machine, fifteen or twenty rods being mounted on the chuck of the machine and ground at one time, as shown in Figs. 6 and 7. The bearing cap is then put in place and the small and large holes are ground internally on machines of the Bryant or Heald type, after a rough-machining operation. A Bryant grinding machine is illustrated in Fig. 8, set up for grinding the large ends of the connecting-rods.

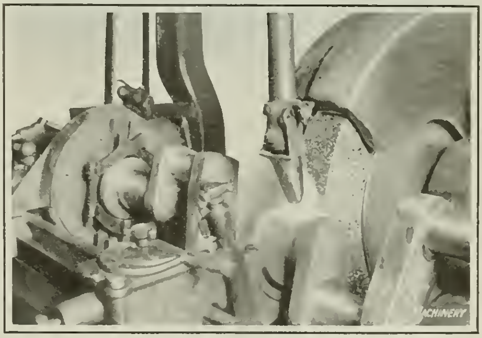

Fig. 10. Grinding Main Bearings of Crankshaft on Plain Cylindrical Machine

Grinding Crankshafts

A typical outline of the operations performed in grinding an automobile crankshaft is as follows: (1) Center the forging; (2) straighten; (3) rough-grind the bearings; (4) turn the flanges and ends; (5) restraighten; (6) rough-grind the pins (sometimes they are rough-turned instead); (7) finish-grind the pins; (8) finish-grind the bearings and outside diameter of the flanges.

Two classes of machines are used—the double-head crank-pin grinding machine, Fig. 9, and the ordinary cylindrical machines, in which the crankshaft is mounted in end-blocks or "throw-blocks," which bring the pins successively into alignment with the headstock and footstock centers. In both cases the wheels are as wide as the pins, and the corners are trued radially in order to form fillets. Wheels slightly over size in thickness are furnished to the operator to allow for truing to the exact width required.

When production warrants the use of more than one machine, it is customary to set up batteries of machines, each performing a single operation. A plain cylindrical grinding machine, equipped with special steadyrests and perhaps a wider wheel than is standard for that size of machine grinds the main bearings, as shown in Fig. 10. A double-head pin-grinding machine grinds the first and fourth pins of a four-throw crankshaft, and another double-head machine grinds the second and third pins. Similarly three machines are used for grinding the pins of a six-throw crankshaft.

A cylindrical grinding machine, which is to be used solely for crankshaft work, is ordinarily equipped with a two-speed hand traverse for convenience in truing the wheel and in locating the work rapidly in position for grinding. Steadyrests of ample width are most essential, and in no class of grinding is the manipulation of the rest more important or capable of greater influence on the quality of work produced. The general principles of cylindrical grinding apply to crankshaft work. For roughing, aluminous abrasive wheels of grain No. 30 or 36 and of hard grade are used. For finishing, aluminous abrasive wheels of medium grade and finer grain give the best results.

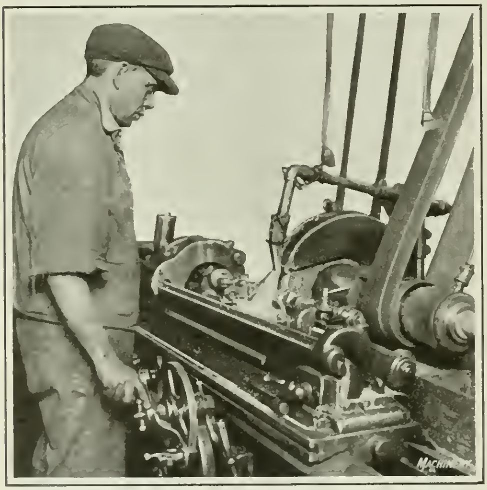

Fig. 11. Grinding Cams to the Correct Contour after hardening

Cam Grinding

Cams are usually rough-ground from the black forging, and considerable material must be removed at a very rapid rate. This is practically a semi-precision snagging operation, and it is accomplished by the use of hard, coarse wheels. After the rough-grinding operation, the cams are hardened. In some shops two grinding wheels are used after hardening, one for semi-finishing and the other for final finishing. In most cases, however, the two operations are performed with the same wheel. Either vitrified or elastic wheels are used.

Cam grinding calls for a high grade of workmanship and great accuracy, as compared with other grinding operations in automobile manufacture. The machine must be operated by a careful workman, who knows thoroughly the art of grinding and applies that knowledge continually. The cam-shaft is revolved at a constant rate, and the proper shape of the cam is developed by a swinging frame controlled by a cam roller following a master cam. The result of this motion is that the camshaft moves toward and away from the grinding wheel, depending on the part of the cam that is being ground.

Fig. 12. Rear View of Grinding Machine showing Mechanism which controls the Cam-grinding Operation

Front and rear views of machines arranged for cam grinding are shown in Figs. 11 and 12. The master cams are located at *A*, Fig. 12, there being one master cam for each cam on the shaft. Cam roller *B* is mounted on a fixed shaft and is set opposite first one master cam and then another. The master cams and the camshaft are carried by a member that is free to oscillate; consequently when a master cam is in contact with roller *B*, the camshaft not only rotates but also moves in and out relative to the grinding wheel, so that cams of the required shape are ground.

This operation calls for much attention on the operator's part on account of the irregular shape of the cam. Although the camshaft is rotated at a constant number of revolutions per minute, the peripheral speed and the nature of the contact varies from one part of the cam to another. On this account it is necessary to adapt the wheel to constantly changing conditions. The operator must be especially careful of the finish, which is closely linked up with the surface speed of the work. Careful truing of the wheel with a diamond, in order to make it cylindrical and to make the wheel face smooth, is essential if perfect work is to be produced.

Effect of Wheel Wear on Accuracy of Cams

The effect of wheel wear on the accuracy of the cam being ground is a peculiarity met with in cam grinding. An error will always exist, regardless of the type of machine or the attachment being used, whenever the periphery of the wheel is used in the grinding operation. This error can be reduced to a minimum, but cannot be entirely eliminated, by regulating the swing of the attachment, so that it approaches more nearly the straight line which passes through the center of the camshaft and the center of the wheel.

If a wheel could be made that would not wear away as a result of the grinding action, there would be no change in the product of such a wheel, provided the diameter of the wheel were exactly the same as that of the one used in generating the master cams. It is not possible to make such a wheel, however, and the slightest amount worn from

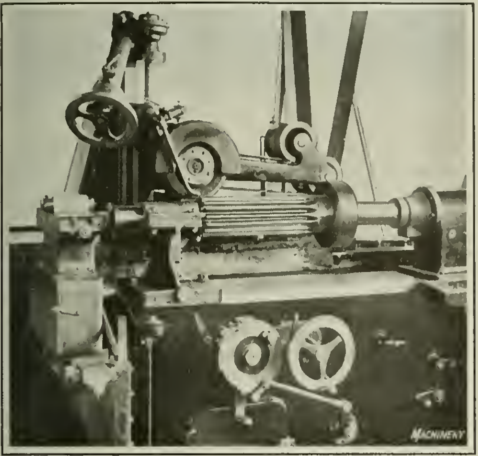

Fig. 13. Gear-tooth Grinding Machine of the Formed-wheel Type

the true theoretical diameter produces a corresponding change in the work. In normal cases with average requirements, the effect of wheel wear does not become evident until one inch or more is worn from the diameter of the wheel, and in many cases the wheel can be reduced as much as four inches in diameter before the error in the cam becomes so great that it will not pass the inspection limits. The foregoing applies to finish-grinding only. When roughing, this error is just as noticeable but is not considered, as finish-grinding is depended upon to correct the error introduced in roughing. For finishing, therefore, a wheel of the proper diameter should always be used, and it should not be allowed to wear to such an extent that the accuracy of the cams will not be within the established limits.

The reason for this peculiarity of cam grinding is obvious. In common types of cam-grinding attachments, the work oscillates in front of the grinding wheel and also revolves about a fixed center. The center holes are concentric with the heel of the cam, while points along the contour and on the toe of the cam are farther away from the center than points on the heel. As the camshaft revolves, the heel of the cam comes in contact with the wheel at a point on the horizontal line drawn from the center of the wheel to the center of the camshaft. Each point on the side of the cam, however, comes in contact with the wheel at a certain distance below this line, and continues in contact with the wheel until it reaches a point the same distance above the line.

It is evident, therefore, that this is quite different from the grinding of cylindrical work, where each point on the periphery of the work revolves at a uniform speed, and immediately recedes from the grinding wheel after having passed the point of contact. As the diameter of the wheel changes, each point on the cam comes in contact with the wheel at a different time, as compared with when the wheel is full size, and furthermore, remains in contact for a shorter or a longer period according to whether the wheel is smaller or larger than the proper size. There are two points that must be considered when finish-grinding is done, if accurate cams are to be produced: The wheels must be soft so that they will cut freely under light pressure, and the work speed must be low, about fifteen or twenty revolutions per minute being the proper speed.

Grinding Operations on Valves

There are usually three and sometimes four grinding operations on a tappet valve. The valve stem is ground in the ordinary type of cylindrical machine, and the valve seat is ground in a special machine or by using an attachment. A typical example illustrating the use of an attachment is shown in Fig. 15. The valve is held at the required angle relative to the wheel, and is revolved by the small belt seen in the illustration. The ends of the stems are ground in various ways, either by surface or disk grinding, or on the face of a cup-wheel, simple fixtures being used to hold the stems. The fourth grinding operation is illustrated in Fig. 16, which shows the valve head being ground by the use of a special attachment. This is not typical of all valve manufacture, but is an added operation performed by many makers.

Methods of Grinding Spur Gears

When the sides of gears are surface-ground, the ordinary type of horizontal spindle rotary surface grinding machine is commonly used. The production, as in all grinding operations in the automotive shops, is rapid. The appearance of the ground surface is pleasing to the eye, because all grinding lines are concentric with the periphery of the gear.

The holes in gears are ground internally, and the wheels ordinarily used for the internal grinding of hardened steel

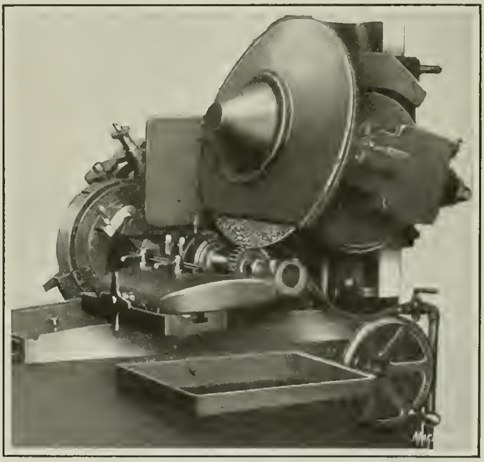

Fig. 14. Gear-tooth Grinding Machine of the Generating Type

give good resuts. If the holes are splined, relatively harder wheels must be used, as otherwise the dressing action of the sharp corners of the spline will cause excessive wheel wear. The larger the number of splines or keyways, the harder the grinding wheel must be to stand up properly.

Gear teeth are sometimes ground to the proper contour after the gears are hardened in order to correct distortions due to heat-treatment, and to obtain accurate tooth forms. This operation requires a special machine. Two general types of machines are used for this purpose, one employing a formed wheel, and the other operating with a generating action. The formed-wheel type of machine, Fig. 13, of the Gear Grinding Machine Co., of Detroit, is so arranged that the grinding wheel is formed to the shape of the gear tooth by means of a diamond held in a truing device, it being possible to obtain any desired shape, depending upon the master form used. The gears are clamped on the machine table and traversed under the wheel, each tooth being ground singly. The number of gears that can be ground at one time depends on their size.

The gear tooth grinder of the Lees-Bradner Co. is a generating type, so designed that the gear rolls bodily past the wheel to obtain the involute tooth profiles. The grinding wheel (see Fig. 14) is set to the pressure angle of the gear, the straight or flat side which does the grinding representing the side of a rack tooth. The combined sliding and rolling action imparted to the work is obtained from a circular segment in conjunction with steel tapes or bands. The segment corresponds to the pitch diameter of the gear to be ground, and is located on the work-spindle. A diamond mounted on a ball socket container, which can be swiveled to any angle, is used to true the face of the grinding wheel. This machine may be used for grinding involute spur gears having pressure angles varying from 14½ to 24 degrees.

Grinding Worm-gears and Spline Shafts

Although there are several grinding operations in making the rear axle (drive shaft, housing, and differential), the grinding of the worm-gears is the only one of special interest. One type of machine used is made by the Reed-Prentice Co. The grinding wheel is mounted at an angle which is governed by the helix angle of the worm thread, and the travel of the work-table is controlled by a cam in the base of the machine. The cam used must correspond with the lead of the worm, the machine being intended for plants where large numbers of duplicate worms are ground. Another cam controls the cross action of the wheel-head for relieving the wheel during the return stroke and advancing it to the cutting position for the grinding stroke. An index device permits the grinding of single- or multiple-thread worms. A formed wheel is used in conjunction with a wheel-forming device. The wheels employed are about the same grade as those used for spline grinding, but the grain size is a little coarser—generally not finer than No. 36.

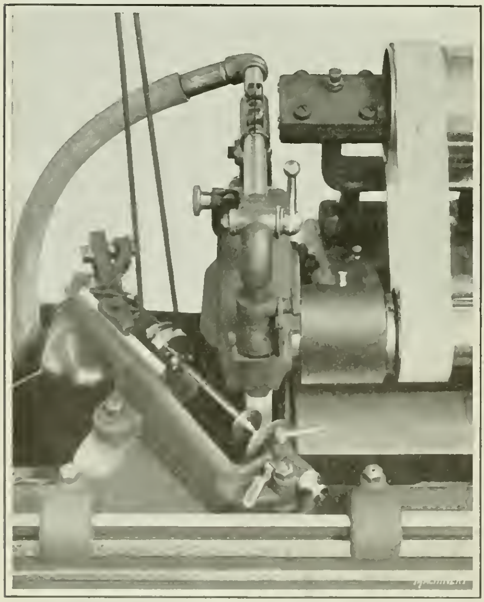

Fig. 15. Attachment for grinding Valve Faces; the Valve is held at the Required Angle and is revolved on Dead Centers

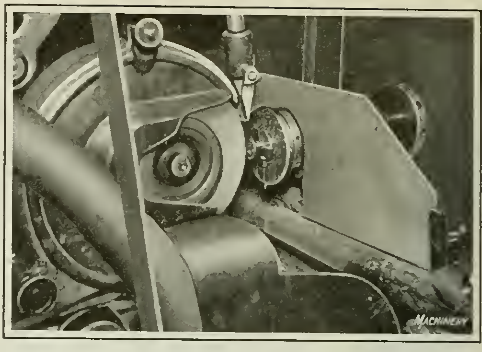

Fig. 16. One Method of grinding Top Surfaces of Valves

The cylindrical grinding operation on spline shafts is no different from that on any of the common pieces ground on a plain cylindrical grinding machine, except that the wheels may have to be somewhat harder to withstand the dressing action caused by the splines. Grinding the splines is a form-grinding operation, the face of the grinding wheel being formed to the correct contour. The multiple-key shaft grinding machine of the Universal Grinding Machine Co. is the type commonly used. The shaft is held in an index work-head, the number of divisions on the dial being determined by the number of keys on the shaft to be ground.

The grinding wheel is formed by two diamonds, one of which forms the periphery and the other the sides. The truing device must necessarily be very accurate. The spline is ground by traversing the shaft back and forth under the wheel, the operation being in reality form surface grinding. The wheel is in contact with the whole contour of the groove between two splines during the grinding, and the corners of the wheel must hold their shape. This operation requires a medium grade aluminous abrasive wheel, the limiting factor being the hardness of the shaft. The grain size is usually about No. 46.

Surface Grinding with Abrasive Disks

Rough surface grinding is finding increased application in the automotive shops, the grinding being done on disk grinders having abrasive disks glued to metal plates. Such parts as pump cases, exhaust connections, gear-cases and covers, cylinder heads, and crankcases are ground in this way. There are two types of machines used, one having a horizontal and the other a vertical spindle. When grinding on horizontal-spindle machines a special work-holder is often used. The part being ground is traversed across the face of the disk, and at the same time is forced against the disk by a hand-lever. This kind of grinding is done dry.

The vertical-spindle machines carry disks as large as 53 inches in diameter, and the parts to be ground are laid on the revolving wheel. When the weight of the work is equal to three or four pounds per square inch of area to be finished, no external pressure is required; but when it is less, weights are laid on the pieces being ground. An exhaust system is provided to remove the dust, the openings being directly beneath the outer edge of the wheel on which a disk is mounted.

Abrasive disks for heavy work such as this are made of artificial abrasives held on canvas or heavy paper backs by means of glue, shellac, or other materials having similar properties. The exact compositions of the binding materials used by the different concerns manufacturing these disks are the result of constant experimental work and are held as trade secrets. The disks are attached to the metal plates by glue, shellac, silicate of soda or a similar material.

Another article on grinding in the automotive industry will be published in the August number.

COMPETITION IN THE FRENCH MACHINE TOOL TRADE

By W. P. MITCHELL *

The French machine tool trade is entering upon a stage of very active competition. French manufacturers have made remarkable progress in machine tool development, and are successfully competing, in point of price, with many lines of American and British machines, and in some cases with German machines as well. For special and high-duty machinery, France must still look abroad, as the comparatively small demand in France for machinery of this type would not warrant the French manufacturers entering these fields.

The drop in the value of the mark, as compared with the franc, has caused German manufacturers to increase their catalogue prices in a marked degree, so that many German-made machines are now higher in price than similar machines of French manufacture. This, of course, is partly due to the fact that German machine tools over 2200 pounds in weight pay a duty of 64 francs per 220 pounds, while similar machines from America and England pay a duty of only 16 francs per 220 pounds.

The average lathe or grinder of German manufacture in the French market is selling in Paris at from 20 to 30 per cent less than the American product of similar type, but the French áre now making machines that sell for from 20 to 30 per cent less than the German machines. Hence French machine tools are prominent in the market at present, although American milling machines and grinding machines are preferred to any French machines, even though the French prices are from 40 to 50 per cent less.

Prices of Machine Tools in France

It is evident that the adverse exchange rates, the French tariff, and the high freight rates are the main causes for the difference in prices of French and American machines. This has aided French builders to capture a very considerable part of their home market. A few comparative prices of American and French machine tools of similar type may prove of interest. A French turret lathe selling at 9500 francs competes with an American lathe selling in Paris at 12,220 francs. A French 40-inch planer with a 10-foot bed is sold for 25,000 francs, while an American 36-inch planer with the same length of bed costs 40,700 francs. A French 4-foot radial drilling machine sells for 25,000 francs, as compared with 38,900 francs for the American product. In general, these comparative prices are for first-class machines in both cases, but French manufacturers have also placed on the market less expensive grades of machine tools of a type that was formerly imported from Germany. The German machine tools at present are priced higher than the French but lower than the American, as already mentioned.

In the following are given additional prices of French machine tools. American manufacturers may make comparisons for themselves with American prices:

14-inch lathe, medium grade	7500 francs
3½-foot radial drilling machine	15,000 francs
15-inch shaper	5000 francs
25-inch shaper	9500 francs
30-inch planer with 6-foot bed	15,000 francs

Prospects for American Machine Tools

Under present economic conditions in France, it does not seem possible to create a better position for American machine tools. The only opportunity that is now apparent is in the case of high-duty machines or special machines that are not being built in France. But American manufacturers in most lines have ever been specialists, pioneers, and improvers, and this will give them strength in the world's markets in all those countries where progress is the watchword; and if France is to hold her own as an industrial country, she must adopt a progressive policy. If France makes proper use of her ore resources and metal industries, no other European country will be able to surpass her in quantity of output.

There is little opportunity of being able to bring American prices in France down to the French level, because it will be a long time before exchange will return to pre-war figures. The French tariff is also a matter to be considered. Manufacturers in all lines in France are asking for further protection. Another possible item in favor of the French manufacturer is the adoption of more efficient production methods. There is continual progress in this respect, which is chiefly manifest in two or three automobile plants. If the eight-hour day law is repealed and there is generally increased production, prices for machinery manufactured in France may come down still further. The same will be the case if the piece-work system is more highly developed. It is true that all of these possibilities are contrary to French routine and tradition, but it might be said that even in France "the old order changeth." In the future, capital in France will have to be content with a smaller return, and the workman will have to be paid more, or living costs will have to come down. A few people in France see this. That is why there is a general transformation of old-time French business methods, or an attempt to make such changes.

French Industrial Fair

The seventeenth industrial fair recently opened in Paris. During the last three years the number of exhibitors has tripled, the number this year being over 4500. Some of the large concerns like the Creuzot and Saint Chamond steel works occupied their own special buildings. This Paris fair (or "Foire de Paris") is destined to become an important part of French industrial life. The exhibitors are either French or of French affiliation. The various metal industries occupied, perhaps, the most important position.

Small electrical tools, drills, brushes, grinders, and polishing machines are now being made in quantities. This equipment is along the general lines of American products. Further development in the manufacture of these small tools depends upon a more general adoption of electricity, and the manufacture of such specialties in France is still in its infancy. Electrical lifting magnets and other elevating and lifting apparatus are being manufactured in France on an increasing scale which is also true of polishing machines of the belt type. It is noted with respect to this latter specialty, as with many others, that the greatest demand is for small tools and other shop equipment (formerly purchased abroad) which may readily be manufactured in small French plants.

One of the most imposing exhibits of heavy machine tools is that of the H. Ernault Co. The exhibit includes engine and turret lathes of large capacity, one lathe having a swing of nearly five feet. A grinding machine made by this firm and having a range of six feet between centers sells for 28,000 francs (about $2500 at the present exchange rate). The Metallurgic Co. of Persan-Beaumont is exhibiting an engine lathe having a swing of 18 centimeters (about 7 inches) and a maximum distance between centers of 1.30 meters (4 feet 3 inches). The price is approximately $650.)

A "Somua" radial drilling machine, capable of boring a hole 7 centimeters in diameter (2¾ inches) sells for 45,000 francs (approximately $4000) delivered in Paris where it is manufactured. The weight of the machine is 11,500 kilograms (25,300 pounds) which an American authority considers inordinately heavy. Another heavy-duty machine of the same make, capable of boring a hole 8.5 centimeters in diameter (3 11/32 inches) sells for approximately $6000. Electrical and autogenous welding machines of French manufacture are appearing in increasing numbers.

A large demand for electrical machinery and accessories is anticipated, following the rapid development of electrical power generation along the Rhone river and the streams of the French Alps and Pyrenees. The southern French railways are planning for extensive electrification within the next five years, and surplus power will be available for industrial enterprises along the route.

Piston Pump Manufacturing Methods

THE double-acting piston pump made by the Goulds Mfg. Co., Seneca Falls, N. Y., which is known by the trade name "Pyramid," consists of a gear-operated cross-head and piston, the stroke of which must be exactly at right angles to the parallel shafts on which the driving gears and pinions are mounted. The cross-head travels on guide-rods extending from holes *A*, Fig. 1, in the main cylinder casting, and the gear and pinion shafts are carried in bearings *B* and *C*, respectively, which are babbitted. The cylinder casting shown is for the 6- by 12-inch pump—the largest size in this style of pump that is manufactured. The piston travels in the brass-lined cylinder bore *D*, and the cylinder head is fitted to surface *E* and carries the stuffing-box. The pitmans are attached to each side of the cross-head, one connecting with a crankpin on an arm of the gear at one side of the pump, and the other with a similar pin in a crank-plate at the opposite side of the pump. The gear and crank-plate are assembled to opposite ends of the driving shaft.

The operations described are those that are performed to establish an even piston stroke at right angles to the gear and pinion shafts. This condition is of vital importance to the satisfactory operation of the pump. After face-milling the base of the casting on a horizontal milling machine, the work is transferred to the machine shown in Fig. 2. This illustration shows two drilling machine units mounted on a common platen, for convenience in machining the cylinder bore, the counterbored surface for fitting the stuffing-box, the guide-rod holes and the cylinder-head bolt holes.

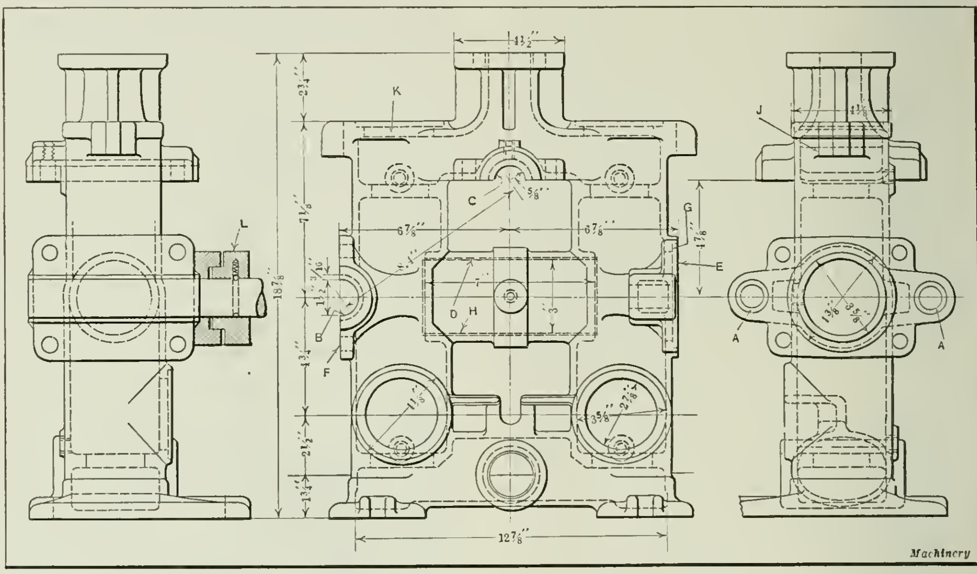

Fig. 1. Detailed Views of Cylinder Casting for Double-acting Pump

Boring and Counterboring Operations

The casting is located on a bridge iron fixture on which it rests on four shims placed under each corner of the rough surface *F*, Fig. 1. Inserted-blade boring heads are used to rough- and finish-bore cylinder *D* and to counterbore *G*. The bars on which these heads are carried are driven by a key in the machine spindle, and are fastened by a hollow-head set-screw, so that they may be quickly replaced. The counterbore has a piloted end that enters the cylinder bore, thus insuring concentricity with the counterbored surface.

Assembling Brass Liner in Cylinder Bore

After counterboring, a No. 16 gage brass liner *H*, Fig. 1, is forced into the cylinder bore. This is assembled by means of a pestle-shaped press arbor *A*, Fig. 2, which has a turned shoulder that seats in the end of the tube, and a shank to enter the machine spindle. The liner is forced into position by the spindle handwheel, after which it is anchored in place by setting over the ends of the liner with a hammer. A special tool having three rolls is used to roll the brass liner snugly against the cylinder bore. This tool is carried in the machine spindle and fed by power. The rolls may be adjusted radially by means of a spindle with a tapered nose, which causes the roll-carriers to expand when the adjusting collar is turned. To contract the rolls, for the smaller diameters of liners, the collar is turned in the opposite direction, and the roll-carriers are forced radially inward by means of springs.

The work is next shifted to the second spindle, where the four bolt holes for the cylinder head and the two guide-rod holes are drilled and reamed, and the guide-rod holes are also counterbored. For this work a jig plate with a cut-out section that straddles the lug *J*, Fig. 1, is employed. The plate is thus located on the casting, and is anchored by a long eyebolt that passes into the casting far enough so that a bar placed in the discharge hole *K* will also pass through the eye of the bolt. As the nut at the plate end of the bolt is tightened, the eyebolt is brought up against this cross-bar and the jig plate secured in place.

Babbitting Fixture

A special fixture is used for babbitting the gear and pinion shaft bearings *B* and *C*, Fig. 1. This fixture is shown in

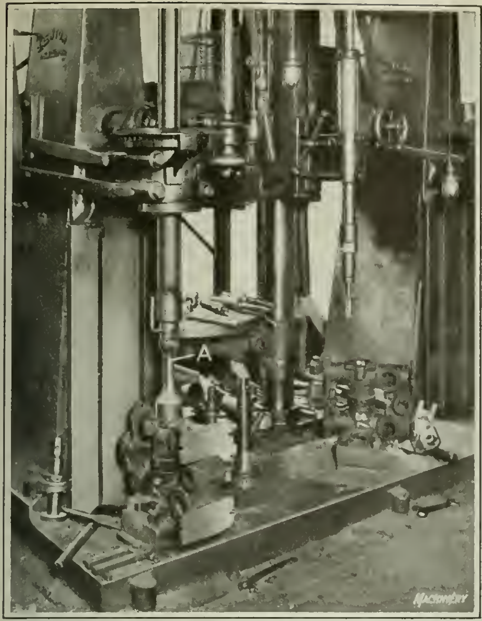

Fig. 2. Drilling Machine on which the Cylinder is bored and the Cylinder Head Bolting Surface machined

place in Fig. 3 with the bearing caps assembled, cardboard packing being used. With this fixture the correct gear center distances are obtained, and the bearings are held parallel with each other and at right angles to the cylinder bore. The side supports of the fixture are T-shaped, and they are attached at the back to a plate by means of which the fixture is fastened to the cylinder-head bolting surface *E*, Fig. 1. It is located by two posts that engage the guide-rod holes at this end of the casting. This plate is shown at *A*, Fig. 3; one of the guide-rod holes used to locate the fixture may also be seen in this illustration.

The side supports or arms have elongated slots by means of which they are bolted to the plate so that they may be placed in the correct position to bring the two arbors central with the cored holes to be babbitted. The center distance of the arbors, which for this size pump is 8.4 inches, is fixed, so that the use of the fixture insures correct relative positions of the gear and pinion shafts. After the caps have been assembled and the fixture has been properly adjusted, the ends of the bearings are closed by special collars. These collars are shown in position on the arbors, and their construction and use is clearly shown in Fig 1 at *L*. There is a pair of collars for each bearing end, one collar of each pair having a spring-snap, which locates it by engagement with a circular groove on the arbor. This collar has a shoulder over which another collar fits so that it may be slid to bear against the end of the bearing. It should be observed that the inner collar is shaped to give the babbitt bearing a built-out surface to receive the hub of the gear or pinion.

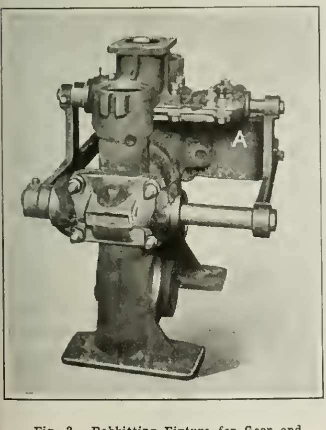

Fig. 3. Babbitting Fixture for Gear and Pinion Shaft Bearings

For luting the joints and for packing in between the slip and loose collars, etc., a composition of ground asbestos and oil is used. This has proved to be more satisfactory as a sealing material than clay, and it is easily prepared and does not harden so as to become unworkable, as is often the case with other luting materials. In the illustration Fig. 3, it will be seen that everything is in readiness for pouring the bearings, including the closing of the joints with the ground asbestos luting material. After the bearings have been poured and the fixture has been removed, no further work is required to obtain the desired relationship of these bearings with the cylinder bore. The amount of machining which is saved, as compared with the use of bronze bearings (when the casting must also be machined) should be readily realized, as well as the accuracy which is obtained.

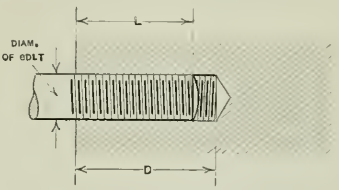
TAPPED HOLES FOR STUD BOLTS

By A. ERICSEN

There seems to be no established practice or rules for determining the correct depths of tapped holes for stud bolts. To insure satisfactory results, this matter should be given more serious consideration than is usually accorded it by engineers, draftsmen, and shop foremen. The accompanying table was prepared by the writer and gives a factor of safety that has proved satisfactory. This table has been used to advantage in making lay-outs, and has been adopted as standard practice in several engineering departments. It is suitable for use in all machine design work, and can be safely employed for high-pressure fittings with standard threads.

TABLE OF THREAD LENGTHS AND TAPPED HOLE DEPTHS*



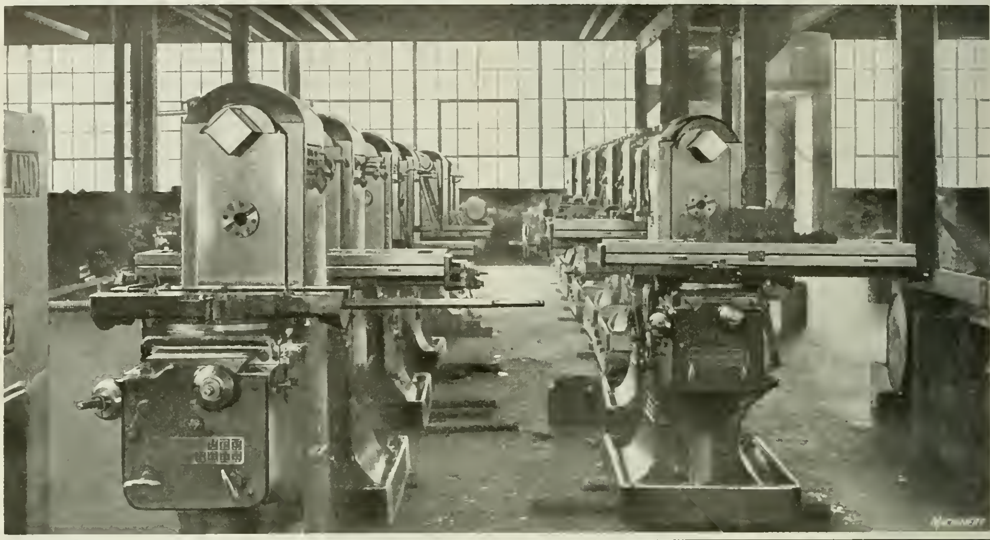
Diameter of Bolt	Cast Steel		Cast Iron		Diameter of Bolt	Cast Steel		Cast Iron	
	L	D	L	D		L	D	L	D
⅛	¼	⅜	¼	⅜	1⅝	2⅛	2⅝	2½	3
¼	⅜	½	⅜	½	1¾	2¼	2¾	2⅝	3⅛
⅜	½	⅝	⅝	¾	1⅞	2⅜	2⅞	2⅞	3⅜
½	⅝	¾	¾	⅞	2	2½	3¼	3	3¾
⅝	⅞	1⅛	1	1¼	2⅛	2¾	3½	3¼	4
¾	1	1¼	1⅛	1⅜	2¼	2⅞	3⅝	3⅜	4⅛
⅞	1⅛	1⅜	1⅜	1⅝	2⅜	3	3¾	3⅝	4⅜
1	1¼	1½	1½	1¾	2½	3⅛	3⅞	3¾	4½
1⅛	1½	2	1¾	2¼	2⅝	3⅜	4⅛	4	4¾
1¼	1⅝	2⅛	1⅞	2⅜	2¾	3½	4¼	4⅛	4⅞
1⅜	1¾	2¼	2⅛	2⅝	2⅞	3⅝	4⅜	4⅜	5⅛
1½	1⅞	2⅜	2¼	2¾	3	3¾	4½	4½	5¼

Machinery

*For wrought iron and cast bronze, use values given for cast steel, and for aluminum and brass, use those given for cast iron.

Broken taps and stripped threads result from incorrectly specified tapped hole depths. For instance, if a ¼-inch stud hole is tapped 1 inch deep or more, it simply means that time is wasted and unnecessary expense involved. When holes for stud bolts are drilled and tapped to a greater depth than necessary, it follows that either a large cavity will be left under the stud bolt, or the threaded part of the bolt will be greater than is required to insure the full holding power.

Aligning and Inspecting Milling Machines



> The accuracy required in the manufacture, assembly, and inspection of high-grade machine tools is generally appreciated. To attain the necessary degree of accuracy, great care must, of course, be taken in the final assembling and fitting operations. The practice outlined in this article is that adopted by the Clark-Mesker Co., Cleveland, Ohio, in building the Cleveland milling machine. The article deals with the final aligning methods and the inspection of this machine.

THE methods employed in the final alignment and inspection of the Cleveland milling machine are described in the following. This machine consists of four main castings—the column to which the knee is accurately fitted; the knee, which carries the saddle, scraped and gibbed to a tongue and groove fit; the saddle (either plain or universal), in the scraped groove of which the table has its bearing; and the table. In establishing a working surface for the table that is level and parallel with the horizontal center line of the spindle and over-arm, as well as at right angles to the vertical bearing on the column, each fitted surface must be held within very close limits of accuracy.

Fitting the Column and Knee

The columns of the machines (and in fact, all castings on which considerable machining is performed) are first planed to produce a suitable surface from which to locate the castings in a fixture, in which position they are not only completely planed, but also bored. The bronze bushings for the gear shafts and main spindle bearings are assembled before the columns are delivered to the assembling floor. The first attention that is given to these castings is to inspect thoroughly the oil troughs and passages for the free flow of oil. This is of paramount importance, because the splash oil system is used in this milling machine. The inside walls of the castings are then scoured and cleaned to remove all molding sand, and a coat of binding material, such as shellac, is applied to these surfaces. The knee castings are subjected to practically the same treatment as the column before any fitting of these two units is done.

The machined castings are left lying on the floor to become seasoned, so that when the bearing surfaces are subsequently scraped in, a permanent set of the fitted bearings will be obtained. The columns are blocked up in the manner indicated in Fig. 1, and the long vertical knee tongue bearing scraped to a master jig. The illustration shows one of these jigs in position on a column and another of similar design resting on the wooden horses at the right. In this operation, the top of the tongue is not scraped, because this surface is not a fitting surface, and between it and the knee groove there is a clearance of from 0.003 to 0.005 inch. The groove of this jig is slightly wider than the tongue on the column so that the jig may be pushed over to form a bearing on one side while scraping, and then to the other side.

In order to maintain parallelism of the scraped surfaces on both sides of the tongue, an adjustable gage consisting of two angular blocks is used. This gage is shown lying on the bearing surface of the second column, from which it will be seen that the two blocks may be set as required by the width of the tongue and that the angular and horizontal surfaces of the blocks are parallel. In rubbing down the surfaces to determine whether there are any high spots, a coating of red lead is applied.

The tongue of the knee casting on which the saddle of the machine has its bearing is scraped to a master jig in the manner just described. This tongue may be seen in Fig. 3 at *A*, but this illustration does not show the scraping operation. The knee is next scraped to the column bearing, a special overhanging angle-plate type fixture being employed by this operation. The fixture is attached to the saddle bearing of the knee as indicated in Fig. 2. This angle-type fixture consists of two cast-iron plates *A* and *B*, set at right angles on a grooved bear-

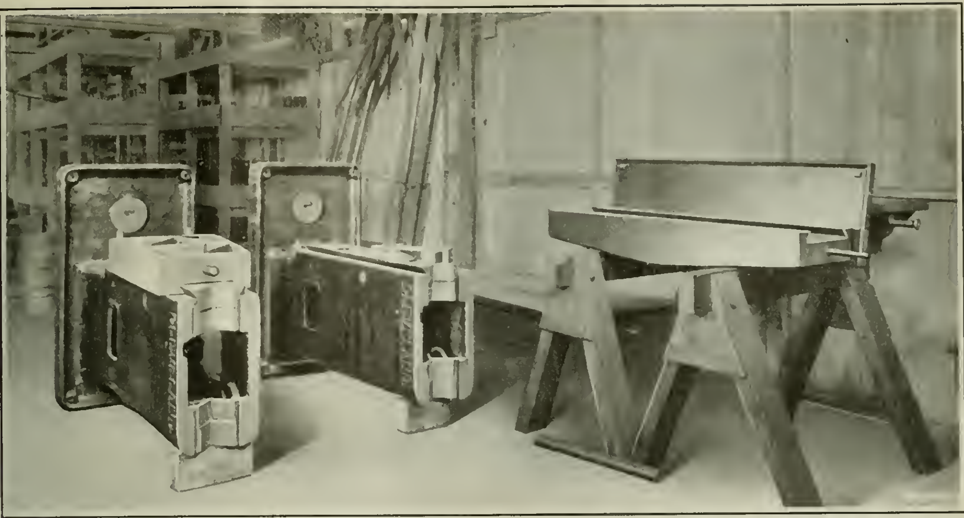


Fig. 1. Milling Machine Columns blocked up in Readiness for Scraping

ing by means of which the fixture is secured to the saddle tongue. It extends twice the ordinary length of the usable part of the column bearing, so that in using an indicator at the extremity of the plates to test the relationship of the saddle bearing and the knee bearing on the column, a greater degree of accuracy can be obtained than if the plates were not thus extended.

In fitting these two castings it is required that the saddle bearing be perpendicular with the column bearing of the knee within a limit of 0.001 inch, and in checking this relationship an angular block carrying a Starrett dial indicator is used. The horizontal plate *B* of the angle fixture has its vertical side accurately scraped and adjusted to be parallel with the tongue on the column. The vertical plate *A* has its under side made parallel with the flat bearing surface of the column. In using the indicator, these surfaces are employed to check the alignment at one side of the column only, as shown in the illustration. When the desired condition has been obtained, a taper gib is fitted between the column tongue and knee groove at the opposite side. If this operation in carefully done and the knee is kept bearing against the tongue of the column at one side, the gib may be fitted with the assurance that the required limit between the saddle bearing on the knee and the column bearing is obtained. The close limits specified in fitting the knee to the column are of vital importance to the perfect alignment of all parts supported on the knee with the machine spindle.

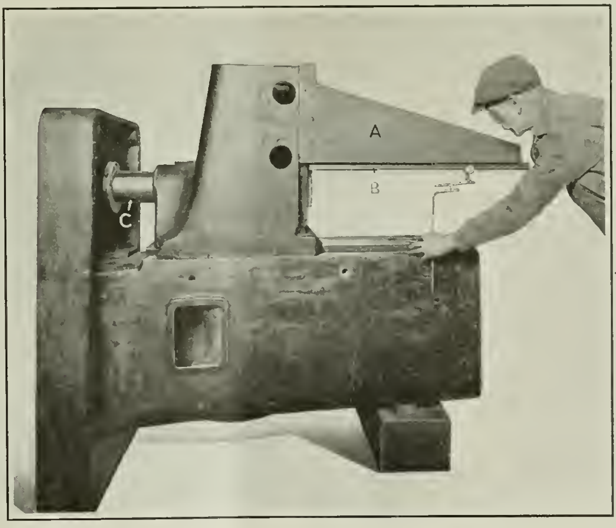

Fig. 2. Fixture for inspecting Assembled Column and Knee

The final operation in fitting the knee is scraping the under side of the flange on the knee guide post *C*, to form an even bearing on the faced boss in the base of the column to which this flange is bolted. This also is an important operation, because the elevating screw for the knee passes through a nut assembled in this post, and it is vital that no cramming of this elevating screw occur. The guide post is then bolted in place.

Fitting the Spindle and Over-arm Bearings

With the column set upright, the spindle bearings and over-arm bearings in the column are aligned relative to the saddle bearings of the knee. The method of testing the relationship of these bearings is illustrated in Fig. 3. The spindle of the machine runs in taper bearings, one at the front and one at the rear of the column. These bearings are scraped to alignment and parallel with the knee, Prussian blue being used in this operation to detect the high spots. A long test bar is then placed in the spindle bearings and a sliding block and dial indicator are used in the manner illustrated, on the left-hand side of the tongue. The allowable limit of parallelism between the spindle bearings and the knee bearings is 0.001 inch.

The planed V-bearings in which the square-section over-arm of the machine is fitted are then scraped to parallelism with the spindle bearings. The equipment used for testing the accuracy of these operations is also illustrated in Fig. 3. The over-arm is

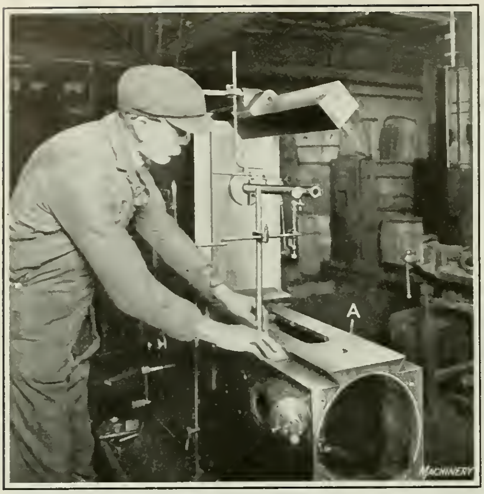

Fig. 3. Test Bar and Indicators used in testing the Spindle Bearings and the Over-arm Bearings in Relation to the Knee Bearings

placed in position and on its top surface an angular slide is seated to which the indicator arm is attached. The same limit of accuracy is maintained on this operation as is required in assembling the spindle bearings, that is, 0.001 inch. It will be understood that this angular slide is moved back and forth on the over-arm with the indicator point in contact with the test bar, before the over-arm cap is assembled. Assembling the cap is the next operation, the only requirement in this case being that the over-arm shall slide freely.

Fitting the Saddle and Table

The machine may be equipped either with a plain or a universal table. In scraping the saddle of the plain milling machine, the top and bottom surfaces are scraped parallel on the bench, a Brown & Sharpe surface plate and red lead being used. The table is next scraped to its bearings in the saddle, an adjustable gage of the type illustrated in Fig. 1 being used to maintain parallelism, and the taper gib is then fitted in place. This work is all performed on the bench.

The left-hand side of the tongue and groove by which the saddle and knee are fitted, is then scraped to a bearing and the tapered gib *A*, Fig. 4, fitted on the right-hand side as shown. In inspecting the accuracy of the fitted bearing of the saddle and knee, the long table furnishes a surface from which the spindle bearings are tested. The gib has been temporarily fitted only, so that in squaring up the table and saddle with the spindle bearings, the saddle may be readily removed as required to correct any inaccuracies that may have been detected in this test.

A long sweep or arm on the test bar in the spindle carries the indicator which is swung from one end to the other of the table, the indicator bearing on the rear vertical planed surface. The table is 50 inches long, and the parallelism between the knee bearings for the saddle and the spindle is thus inspected and held to a limit of 0.002 inch in a length of 50 inches. Since the table surface is planed at the same setting as the saddle bearing surfaces underneath the table, it is possible to use this surface to indicate from without danger of errors due to inaccuracies in machining.

It may be interesting to note that the table castings are seasoned in the open for several months before being machined. They are then rough-planed all over and allowed to set in this semi-finished condition until it is necessary to finish up a quantity to fill an order. As the thoroughly seasoned castings have several surfaces machined at one time by the use of multiple tools, set to a master gage so that the relation between all the surfaces is kept uniform, a high degree of accuracy is obtained.

When the milling machine is to be equipped with a universal saddle (see the heading illustration) in which the table rotates on a swivel, the swivel is first graduated and the zero graduation marked on the universal saddle after the assembled saddle and table have been first set square with the spindle bearings. In setting the saddle and table of a universal milling machine, equipment similar to that illustrated in Fig. 4 is employed, which was described in connection with the scraping-in of the saddle bearings for a plain machine.

Boring Over-arm Pendants—Gear Testing

The over-arm pendant, which supports the cutter-arbor, is bored for the outboard support of the arbor with the set-up illustrated in Fig. 5. The boring-bar *A* is of the fly-cutter type, and is carried in the regular spindle bearings. The over-arm is fed to the cutter by a hand-operated device which is attached to the column of the machine in the manner indicated. This assures absolute parallelism between the arbor support and the spindle bearing.

The speed gears, which are of the sliding type and controlled by an automobile shift lever handle, are carried in the column of the machine, and the feed gears are located in a box at the front of the knee. Both sets are inspected for backlash and running qualities by means of a master gage which is a replica of the gears used in the particular train being tested. The gage illustrated in Fig. 6 is for testing the speed gears. It is used by simply placing the various gears on their respective shafts, which rest in open bearings on the master gage, and revolving them by hand. By this simple but effective means the action of the entire gear train can be clearly observed.

Running-in Test and Final Inspection

After the machine has been completely assembled and is ready for operation, it is given a running-in test at all speeds without load. During this trial run the inspector is required to make observations of every part of the machine that it is possible for him to inspect, and enter a notation opposite every question on a special report sheet. For example, in inspecting the column he must report, among other things, on the following items: Supply of oil in the column; adjustment of starting friction clutch; operation of gear-shifting bars by means of the ball lever, sockets, etc.; operation of the speed reverse mechanism; alignment of the

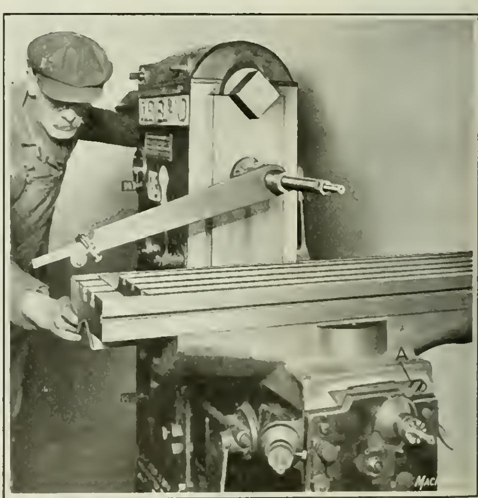

Fig. 4. Arm and Indicator used in squaring up the Table with the Spindle

spindle hole by means of a taper gage (here the diameter and taper of the spindle bearings must be noted); and amount spindle runs out at the mouth and at the end of a 15-inch test bar.

The inspector must also note whether or not the spindle bearings become overheated after a run of thirty minutes and must state if the machine has been run five minutes on each speed. The quiet running qualities of the gears when running idle and when under load must be stated on this report, as well as the correct rotative speed for the driving pulley. There must be no leakage of oil at any place in the column and the cutter lubricant pipes and valves must be a good fit at the joints. A tolerance of 0.002 inch is allowable in lining up the hole in the pendant for the arbor support with the center of the spindle. The distance the spindle nose extends beyond the face of the column must not be more than 0.032 inch under the nominal length. The inspector must furnish a definite answer concerning both these details and he must also check the diameter of the spindle nose to within limits of plus 0.000 and minus 0.0005 inch. The points mentioned only partly cover the complete questionnaire which has to be filled out by the inspector for every machine built.

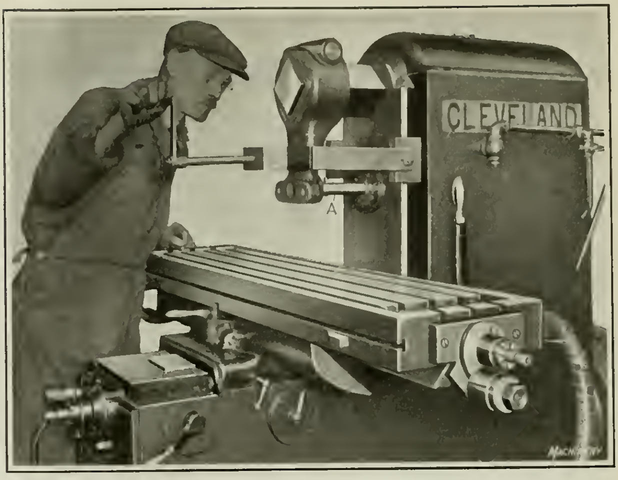

Fig. 5. Boring the Arbor Support Hole in the Over-arm Pendant

Inspection of Knee, Saddle, and Table

A few of the questions contained in the inspector's report relative to the knee, saddle, and table are:

Is knee gib adjusted properly?

Does knee operate smoothly and at uniform resistance throughout its full travel?

Is saddle gib properly adjusted?

Does saddle operate smoothly and with uniform resistance throughout its travel?

Does cross-feed screw work smoothly and with uniform resistance throughout its travel?

Have graduations on saddle been correctly stamped?

Does table screw handwheel run true?

Does table quick-return bracket work smoothly?

Are slots in table correct to gage?

A similar set of questions pertains to the gearing and operation of the gears in the feed-box, and each of these questions must be answered in full. The following details regarding alignment should receive the inspector's attention, and where deviation from true alignment is noted, the amount of this deviation must be reported, as, for example, when testing the alignment of the spindle with the top of the ways on the knee, with the side of the ways on the knee, with the top of the over-arm, and with the side of the over-arm, on each of which there is a limit of 0.002 inch. In inspecting the top of the knee relative to the face of the column and to the ways of the column, the amount of error in 15 inches width must be noted. Similarly, the top of the table must be checked for parallelism with the top of the knee, and the variation in a length of 24 inches entered on the report. For checking the top of the table relative to the spindle and the T-slots of the table relative to the spindle, diagrammatic sketches are contained on the report so that the corner of the table which is high or low may be indicated.

Horsepower Tests

The inspector must further report the range of hand and power feeds for the longitudinal, cross, and vertical feeds for the table. All data regarding horsepower tests, both with and without load, such as the spindle revolutions per minute, kilowatts, voltage, and horsepower transmitted must be furnished. When working under load, a description of the material used in the test is required, as well as the cutter diameter, amount of stock removed, feed in inches per minute, speed of cutter in feet per minute, etc.

After the machine has passed these exhaustive tests and before it is ready for crating, special care must be given by the inspector to the tools and attachments to be included in the consignment, and the condition of these, as well as the provision for attaching them to the machine, must be noted. The entire list should be carefully checked with the shipping list and any deficiencies or improper parts reported. The machine is tested for appearance, with respect to painting, polishing, condition of screw-heads and nuts, and the rustproofing of parts so treated. Final provision is made on the report for the inspectors to furnish a summarized statement or to make notes regarding special points not fully covered in the report form. The inspector then signs and dates the reports, and these form a complete reference in case any question relative to the operation of the machine should be raised after it has been put into regular use.

Opportunities in the Machine Tool Industry

By FRED A. GEIER, President, Cincinnati Milling Machine Co., Cincinnati, Ohio

WHAT are the opportunities in the machine tool industry for young men about to choose their life work? This question is debated in the mind of many a young man today, and naturally so, because of the depression through which the machine tool industry has passed.

The main point that should be considered is the fact that the machine tool industry is the foundation upon which all other machine-building industries are built. It may have periodic depressions, but it also has periods of prosperity, and even during the depressions the men who have made a place for themselves in this industry as capable engineers or shop executives have retained their place. At the present moment some of the large firms in the field are looking for capable designers; and except for the unusual but somewhat uncertain opportunities that may be offered by some industry that has a sudden boom when it first looms up on the industrial horizon, it is doubtful if any other engineering industry offers a better field for earnest efforts, initiative, and ability than the machine tool industry.

The Type of Man who will Succeed

The conditions created by the war had a far-reaching effect upon men's minds. The tendency toward less seriousness of purpose is apparent everywhere, and the young men just starting life have been especially affected. The ease with which some fortunes were made during the war, either through pure speculation or through advantage being taken of the abnormal demand for goods of all kinds, created an impression that it will take many years to eradicate. Many seem to believe that it is possible to obtain a comfortable living, and even wealth, without a great deal of effort. The desire for pleasure and entertainment is greater than ever. The spare time of the younger generation is spent almost exclusively in the pursuit of pleasure, rather than in preparing for greater responsibilities in a successful business or engineering career. There is much less inclination to devote spare hours to study than in the years preceding the war, and the tendency to avoid serious effort is marked.

These tendencies of the times, however, create even greater opportunities for those whose minds are capable of serious endeavor, because there is actually less competition for the important places in the industrial field. The man who applies himself with earnest effort to his work stands out more definitely and will gain recognition more easily than in past years when such effort was more general. But it must be remembered that in the years to come, the ease of the war period will cease, and no success can be earned without hard and persistent work, any more than it could be attained without effort and application previous to the war. To the young man with a serious purpose, the machine tool industry offers at the present time an opportunity for usefulness and development at fair compensation.

Stability the Keynote in the Machine Tool Field

After all, the machine tool industry is one of the most stable of industries. Taking the established concerns in this field, the number of failures over a period of years has been exceedingly small. But it is not a "get-rich-quick" industry. It is not a speculative industry like the oil and mining business. There are no opportunities for gambling chances, but the young man choosing his life career should remember that for one gusher that may give wealth and easy riches, there are a hundred dry oil wells. For one lead of ore that furnishes profits to the mine operator, there are a hundred dead leads. There is an uncertainty that is not present in the machine industry. The speculative fields offer opportunities for a few men who are lucky. The stable industries—like the machine tool industry—offer steady employment with fair compensation to those who make good, and they need not take the gambling chances that are taken by those who look for "get-rich-quick" opportunities. In addition, the man engaged in the machine tool industry has the satisfaction of feeling that his work is necessary and useful to the world, because this industry is the basis upon which the entire civilization is built in a machine-made world like ours.

This satisfaction can never become part of the life of the speculator or the man engaged in enterprises the main purposes of which are to provide profits for the promotors. Even when these enterprises are not entirely dishonest in purpose, they are frequently entirely useless as far as the world at large is concerned, and are often intended to serve no other purpose than to provide an easy living for those who are able to influence the minds and pocketbooks of credulous investors and buyers.

The machine tool industry, on the other hand, is based on the one fundamental fact that it receives nothing except for value delivered. It must make good from month to month and from year to year. It must continue to produce machinery and appliances that will save money in production in other shops, and it can be based on no other qualities than honesty, integrity, and initiative.

The Needs of the Machine Tool Industry

Because of the purpose and position of the machine tool industry in the industrial structure, it constantly needs young men of a serious frame of mind, determination, ability, and progressive ideas. It is an industry that can never stand still. It therefore offers unusual and constant opportunities for the development of new ideas, and it places no limitations on the display of initiative.

We have just begun to develop machine tools along high productive lines. Only a few of the machine-building industries are as yet using machine tools to the best advantage, but as other industries become more and more specialized, the demand for machine tools that will produce more rapidly and more accurately will increase. In spite of the tremendous advance that has been made in machine tool design and construction during the last twenty or thirty years, perfection has by no means been reached in present designs. The years to come will doubtless see a great improvement in the capacity of machine tools. To carry this work forward, men are needed who have imagination coupled with a serious purpose. They must be able to conceive of new ideas; they must have the ability to do research work and to determine by experiments and analyses the lines along which the development of machine tool design must be carried on in the future.

The places of those men who are now the leaders in the field and who have brought the machine tool industry to its present point of development must be taken by a younger generation with new ideas and new enthusiasms. For men of the right type the machine tool industry offers an opportunity for a steady, honest, and useful life-work, with the satisfaction that comes from having filled a needed place in the world. As the industry grows and develops, the opportunities for greater usefulness and greater success will also grow.

Opportunities in the Machine Tool Industry

By J. B. DOAN, President, American Tool Works Co., Cincinnati, Ohio

THE question has been asked whether I consider the machine tool industry a worth-while field for young men to enter. Does it offer an opportunity to young men about to choose their life work?

To one who has been engaged in this industry for thirty years, this seems at first thought almost an unnecessary question, because there can be only one answer. But on further thought it will be realized that it is a natural question for a young man to ask, because if he has seen the industry only in the present depression, he may hesitate to become identified with it, even though his inclinations and abilities would fit him unusually well for this field. It is a peculiar trait of human nature to think, during a period of prosperity, that prosperous conditions will last forever; and on the other hand, in times of depression, it is natural to believe that business will remain in that state forever. In view of this, a few words from one who has been identified with the machine tool industry for many years may be helpful to younger men.

Fluctuations in the Industry

Practically every business has its high spots and low spots. This fluctuating condition is more pronounced in those industries whose products are not quickly consumed, and it is well known that machine tools have a comparatively long life—longer in fact than they should have for really economical production. Hence, the fluctuations are greater than in a business where the product is such that it is consumed practically as soon as it is produced, like agricultural products and clothing. As a general rule, the further an industry is removed from the ultimate consumer, the more marked are its fluctuations, and the building of machine tools being the basic industry—the beginning, so to speak, of all production in the manufacturing field—is therefore subject to more marked periods of prosperity and more definite and prolonged depressions than most other lines of manufacturing activity.

Constant Development in the Mechanical Field Requires Machine Tool Equipment

Anybody who knows anything about mechanics and mechanical devices realizes that they are becoming more and more an essential part of civilization; and they will probably become even more a part of everyday life in the future. New mechanical devices are constantly being developed to perform manufacturing operations formerly done by hand; to provide pleasure and entertainment, like the automobile, the phonograph, and the radio telephone; or for greater convenience like the many electrical devices for household use which have been placed on the market during the last few years. Machine tools are required for making all these devices. The future of the machine tool industry therefore is assured, because the demand for machine tools is as fundamental as the demand for agricultural products, clothing, or any of the prime necessities of life. The only difference is that the demands for the latter are constant, whereas the demand for machine tools is fluctuating.

The Need for High-grade Men in the Machine Tool Industry

The machine tool business is a difficult one. It requires a high grade of mechanical, executive, and business ability, and the men holding responsible positions in it must be capable of looking forward into the future. Because of the extremely high cost of designs, drawings, patterns, jigs, fixtures, time studies, etc., mistakes are very costly. This industry, therefore, requires the best type of brains—a type which should be well paid.

Both on the commercial side and on the engineering side the requirements are high. Men are needed who are capable of designing correctly the kind of machines for which there is a demand, and which will perform and produce in the customers' shops in such a way that a future demand is assured. Men are also required who are capable of manufacturing these machines in an economical manner, so that they can be sold at a price that will return a large enough profit for accumulating a sufficient surplus in good business years to tide the industry over the dull periods. This field also requires the highest type of selling ability, so that a properly designed and economically manufactured product may be sold in sufficient quantities to produce sufficient returns. All this requires a type of brains that can demand a satisfactory return for services rendered.

Service of this Industry to Other Industries

The abilities of the men engaged in the machine tool industry must also be such as to counteract the influences that are tending to break down the high standards of the industry in times of depression. At present the machine tool industry is passing through a discouraging period, because purchasers, instead of encouraging the development of better machines by being willing to pay a fair price, are doing just the opposite, and by attempting to beat down the price are hampering the development of better and more productive machines.

If this policy were pursued for a sufficient length of time, it would bankrupt the entire machine tool industry, and the principal sufferers in the long run would be the users of machine tools who must have them in order to produce economically and in sufficient quantities the goods which they sell. It requires great ability to counteract these influences that are tending—unintentional though it may be—to wreck the industry. Buyers of machine tools must be informed of the truth of the situation in such a manner that they are able to see that the welfare of the industries in which they themselves are engaged depends upon the welfare of the machine tool industry. To carry on this work among machine tool buyers requires a type of man of unusual abilities who must be well paid.

To sum up the whole situation, the machine tool industry unquestionably offers inducements to young men who have the proper qualifications. Because of the many difficult problems that confront this industry, there is plenty of room in it for men who have foresight, courage, stamina, and integrity. This type of man, in whatever industry he is engaged, must be well paid, and because the opportunities to display ability are greater in the machine tool industry than in many other fields, the possibilities for success are also greater. Gradually the industry is becoming more and more aware of the fact that, with proper management, it can bridge over the periods of depression by foresight and conservative action during the prosperous years. The machine tool industry should be judged, not by its periodic booms and depressions, but by its constant development and progress over a long period of years. The development of the machine tool industry in the United States during the last thirty years is proof of the possibilities, the stability, the usefulness and the permanency of this industry.

HOOVER ON COOPERATION

In his address before the executives and secretaries of trade associations at the recent Washington conference, Secretary Hoover referred to the cooperation of his Department with several organizations that have appointed special committees to give "direction and strategy to the agencies of the Department of Commerce abroad on behalf of the whole industry," thereby facilitating closer cooperation between the Department and the automobile and rubber industries, as well as others.

Secretary Hoover is not trying to force this kind of cooperation upon the industries. He is offering a service that has never yet been performed by our Government, although before the war similar services were rendered by the German Government to its manufacturers, which helped the wonderful extension of their foreign trade—that in machine tools alone having increased over 1000 per cent between 1904 and 1914. Cooperation cannot be effected by one party to the effort alone, and American manufacturers who are interested in foreign trade must show their active interest in this work, or it will amount to little.

The machine tool building industries represented in the Department of Commerce by the Industrial Machinery Division have not formed a special committee to cooperate, although apparently it would be of considerable advantage to them, and especially to those engaged in the metal-working machinery field. The larger manufacturers may be able, through special representatives, to investigate foreign markets sufficiently for their needs, but the great number of small manufacturers in the metal-working machinery field cannot afford to undertake such work, nor to maintain an information service that keeps them in touch with foreign developments affecting them.

If the smaller manufacturers are to be kept informed about the possibilities in foreign markets, a cooperative arrangement with the Department of Commerce is of great importance. A special committee to keep in close touch with the Department, and especially with the Industrial Machinery Division can greatly help the latter in its work, by pointing out specifically the lines of inquiry along which the Department can be of the greatest service. Several of the leading trade associations and societies in the mechanical engineering fields, such as the National Machine Tool Builders' Association and the American Society of Mechanical Engineers, might well unite in forming such a committee, the members from the latter society representing manufacturers of industrial machinery and equipment other than machine tools. This effort should especially appeal to all manufacturers who are interested in exports, and the mounting values of foreign exchange mark the present as the time when such an effort should be initiated.

* * *

BUILDING UP GOOD WILL

Good will is worth millions to many great enterprises, and is a substantial part of the assets of many small ones. This factor of value is based almost entirely upon the confidence of the buyer in the manufacturer or dealer, and every machine tool builder knows well that the closing of a sale is often only the beginning of his relations with the buyer. The machine sold must make good in the customer's shop. It must prove to be the kind of machine best suited for his work, and if it develops unexpected defects, the seller must make good or lose the buyer's confidence.

In building up good will in the machinery field no factor is more important than the suitability of the machine to the customer's needs. If it is too heavy or too light, or in any other way unfitted for the work it was bought for, it is a poor sale and the manufacturer may eventually lose more than his profit, because the customer will soon learn that he made a mistake which he could have avoided if the seller had cared to give him honest advice as to the kind of equipment best suited to his needs.

The truisms mentioned above apply also to a variety of products. The manufacturer of leather belting, who is familiar with the conditions under which his product is to be used, can give advice that will save his customer money. If the manufacturer of gearing is familiar with the kind of service the gears are required to render, he may be able to advise his customer on a selection of gears that will be better for the work than those the buyer originally intended to get. Sometimes for this reason the sale may be smaller and the profits less; but the profit chargeable to good will cannot be estimated in dollars and cents, for the customer who has been given honest advice will return with more business. Some far-sighted manufacturers refuse to make sales of their product for uses in which they are unlikely to make good.

* * *

THE VALUE OF APPRENTICESHIPS

What are the chances of success for the boy who completes a regular apprenticeship, as compared with one who simply goes to work in a shop as an operator and expects to pick up some knowledge of the trade while earning a regular operator's wage? Voluminous statistics would be necessary to answer this question accurately; but the experience in a few plants where records have been kept of apprentices shows the great value of systematic training in shop work. In a comparatively small shop in Michigan, the proprietor made it a rule to take in a certain number of apprentices every year. He put them through a rather strenuous course of training and many of the boys dropped out, partly because the work was hard and partly because they could earn more as machine operators in other shops; but the success of those who completed their apprentice course proved that they did not pay too high a price for their training. All but one of those who finished their apprenticeships of four years are today either superintendents or foremen, and five of them own their own shops.

Another manufacturer states that about 50 per cent of the apprentices taken into his plant completed their apprenticeship, and of those who did so the majority are today either superintendents or foremen, or hold other positions of responsibility. A Cleveland machine tool manufacturer who has maintained an apprenticeship system for forty years, has kept a record of those who have learned their trade in his shop, and the list includes several well-known manufacturers and shop superintendents, as well as a large number of successful salesmen and foremen.

The National Metal Trades Association is working successfully to interest its members in a systematic plan for establishing apprenticeships which doubtless will prove of practical value, both to the young men who take up this training and to the industry generally. This plan should have the support of all manufacturers.

Selling Machine Tools by Demonstration

By OGDEN R. ADAMS, Rochester, N. Y.

DURING the past a great deal of effort has been made to sell machine tools by letters, catalogues, and circular matter, but little or no attempt has been made to demonstrate to the prospective customer what can actually be done with the machine tools on the market. The only way in which a customer can be thoroughly convinced as to the superior qualities of a machine is by an actual demonstration of its work. This sales method has been almost entirely neglected in the United States.

The entire mechanical field has been advancing rapidly during the last few years, and the machine tool manufacturer, representing a basic industry, has had to step lively in order to keep ahead of the procession. He has been able to do this, however, and there are a great many machines on the market today that are far superior to those that were available, say, ten years ago—or even five years ago. In consequence of this, hundreds of men who have been running shops that were well equipped with modern machines several years ago, and who have settled down to what they consider to be approved methods of production, are not familiar with the improved types of machines which the machine tool manufacturers have placed on the market during the last few years. These new machines in some cases are improvements on former types; in other cases they have been developed from the ground up, representing entirely original ideas, and are placed on the market as competitors of other types of machines that were formerly used for doing the same kind of work.

Modern Method of showing, by Actual Demonstration, what Results can be obtained from Different Types of Machine Tools

The Value of Dealers' Demonstrations of Machine Tools

A few years ago I conceived the idea of inviting the manufacturers from various parts of the country to my showrooms in Rochester in order to give them an opportunity to see newly developed machines, operated by expert demonstrators, performing actual work. My experience has taught me that this method is a valuable one, and that by following some such practice it is possible to create a great deal of interest, not only among the local and nearby manufacturers but among their employes as well. These men have gone to considerable trouble to come to the annual demonstrations, which now seem to take the form of an annual reunion of the men. Some come in intending to stay a few minutes only, but when they see the value of the demonstration, they remain for hours. This bringing together of men from different factories also gives them an opportunity to exchange views and ideas along mechanical lines, which in many cases has proved mutually helpful.

General Principles of Machine Tool Demonstrations

When a machine tool demonstration is arranged for in the show-rooms of a machine tool dealer, it should be planned with considerable care. Experienced mechanical men do not wish to see a standard machine tool being operated. It is of no particular interest to them to see an ordinary lathe producing an ordinary chip. What they wish to learn is how rapidly good work can be produced on different types of machine tools or how accurately work can be produced by an average operator. They want to know about the newest types of machines for producing work of a certain quality in the quickest possible time. They are interested in the safety devices for the protection of the operator, and in all kinds of improvements in design for the rapid and convenient handling of work. Furthermore, they are interested in the conservation of floor space, a point that can be very effectively demonstrated in the exhibition rooms of a machine tool dealer.

All these various things have been successfully demonstrated and it is not a mere theory that such demonstrations can be made successful. The machine tool manufacturers naturally are enthusiastic over the opportunity to have their machines exhibited, and generally they are glad to supply demonstrators and experts to explain thoroughly the operation of the machines and the new ideas that have been incorporated in their design. Another advantage of this local demonstration is that it is possible for the dealer to obtain local work for demonstration purposes. He can then show by actual performance how it can be done to better advantage on the machines in operation in the show-room than it is at present in the prospective customer's shop.

Taking Care of the Human Side

In making a success of a machine tool demonstration in the show-rooms of a dealer, it is necessary, in order to sustain the interest, to furnish not only serious food for thought to the visitors, but also to appeal to their sense of humor and to provide for the "inner man." Educational features should be introduced in the nature of talks by authorities, and these should be illustrated, if possible, by stereoptican views. In the demonstrations held in the writer's showrooms in Rochester, an opportunity has also been provided for testing the manual skill of the visitors, or their quick brain action in overcoming some difficult problem, and to stimulate interest prizes have been awarded for the performance of some particular kind of operation.

It is important, if these demonstrations are started, that they must not be considered as a single effort held only once, but they should be made an annual function of the machine tool dealer's business, and should be conducted in a dignified, constructive, and instructive manner. In Europe machine tools have been sold by demonstration for years, and in a great many of the European show-rooms machines are under belt at all times, and expert operators are employed who can start and operate any machine when a customer calls.

Such methods would be of great value in the United States as well. At first, however, it might be necessary to limit the efforts to annual demonstrations, while later on permanent demonstrating rooms could be maintained. A few of the manufacturers of machine tools now maintain demonstrating rooms in their factories, but I believe, as the pioneer in this country in the adoption of a dealer's demonstration, that I have struck the right keynote for the most effective advertising covering a limited territory, and the right method in which to instruct prospective customers in regard to the machine tools handled. The results obtained thus far have thoroughly proved the accuracy of our opinions and the success of our endeavors.

By carefully planned demonstrations, it is possible to make every city of any size in the machine shop centers of the country an attractive center for machine tool buyers. By such efforts local dealers would be able to obtain a stronger grip upon the local machine tool trade, and they would come into closer contact with their customers.

GERMAN MACHINE TOOL PRICES

By MACHINERY'S Special Correspondent

Berlin, June 10

The German machine shops are fully occupied, but there are complaints about a scarcity of coal, a falling off in export orders, an increasing scarcity of credits, and slow collections. Many plants are working over-time. Sales are made at sliding prices only, and the domestic prices in many cases exceed those offered foreign buyers. As an example may be mentioned aluminum goods, which have become too expensive for domestic buyers.

The demand for locomotives is brisk. Several orders for bridges for South America have been booked, as well as orders for railway equipment; but Belgian competition is becoming keener, and a large Belgian iron works has underbid German firms in many cases. One bid on rails for Bulgaria shows the Belgian price as 14 per cent below the German. On bids for railway car wheel tires, pipes, metal ties and plates, German prices in recent bids have been from 16 to 34 per cent above Belgian prices.

The price per pound of machine tools, as expressed in marks, is constantly rising. In many instances it is now from 28 to 32 marks per pound. Some examples of prices current in the month of April are given in the following:

Prices of Stock Machines

18-inch engine gap lathes (with feed-rod), distance between centers 60 inches, weight 3740 pounds, 70,000 marks (present exchange, about $235).

Bolt-cutting machines, height of centers 8 inches, distance between centers 50 inches, weight 2000 pounds, 43,000 marks (present exchange, $145). The same type with height of centers 6¼ inches, distance between centers 24 inches, weight 1540 pounds, 38,500 marks (present exchange, $130).

Planers, working length of table 60 inches, width 36 inches, working height 30 inches, weight 9900 pounds, 210,000 marks (present exchange, $700).

Shapers, stroke of ram 22 inches, weight 3300 pounds, 75,300 marks (present exchange, $250).

Oil-grooving machines with single-pulley drive, weight 2530 pounds, 50,000 marks (present exchange, $165).

Prices of Machines Made to Order

Small thread-cutting machines for cutting brass threads up to 0.20 inch in diameter, 3600 marks (present exchange, $12); up to 0.80 inch in diameter, 10,200 marks (present exchange, $34).

14-inch production lathe, distance between centers 36 inches, weight 2090 pounds, 48,400 marks (present exchange, $160).

24-inch engine lathe, distance between centers 50 inches, weight 8360 pounds, 190,300 marks (present exchange, $635).

18-inch engine lathe (Wohlenberg), distance between centers 60 inches, weight, 3475 pounds, 68,100 marks (present exchange, $225).

Radial drilling machines (high-duty), with motor drive, working radius 72 inches, working height 80 inches, weight 15,840 pounds, 440,000 marks, not including electrical equipment (present exchange, $1465).

Radial drilling machines, with motor drive, capable of drilling holes up to 2.6 inches in diameter, working radius 70 inches, working height 64 inches, weight 10,780 pounds, including electrical equipment, but without table and foundation plate, 308,250 marks (present exchange, $1025).

Radial drilling machines for drilling holes up to 2 inches in diameter, working radius 88 inches, working height 56 inches, weight 6775 pounds, 145,150 marks (present exchange, $485).

Plate-straightening machines for rough plates, ¼ inch to ¾ inch thick, 106 inches wide, 1,203,000 marks (present exchange, $4000).

Duplex nut milling machine, table surface 10 inches wide by 44 inches long, weight 4350 pounds, 98,500 marks (present exchange, $330).

Circular plate shears capable of handling plates 0.120 inch thick and 40 inches in diameter, weight 814 pounds, 22,000 marks (present exchange, $73).

Planer, working length of table 100 inches, width 60 inches, and working height 50 inches, weight 26,400 pounds, 560,000 marks (present exchange, $1865).

Cold saw (heaviest pattern), diameter of saw 48 inches, weight 18,525 pounds, 285,300 marks (present exchange, $950).

Lathe chuck (Cushman type), diameter 2¾ inches, 600 marks (present exchange, $2); diameter 10⅝ inches, 2100 marks ($7); diameter 18⅞ inches, 7500 marks ($25).

* * *

In a recent number of the Journal of the Franklin Institute, mention is made of the application of what has been termed the "ultra-micrometer" to the measurement of small increments of temperature. This is an electrical device so sensitive that it is said to be possible to detect a change in temperature of one-sixteen thousandth of a degree Centigrade or a change in length of one two-hundred millionth of an inch. By this arrangement the expansion coefficient of copper can be measured by raising the temperature a single degree.

Making Radio Parts

By FRED R. DANIELS

The Use of Lathes and Other Machine Tools in Radio Shops

PERHAPS the most general use of lathes in radio manufacture is for winding tuning coils, rheostat coils, etc. The winding of a tuning coil, as done in the plant of the DeForest Radio Telephone & Telegraph Co., is shown in Fig. 1. These coils are wound on uncolored bakelite tubes. The uncolored material is used because it has been found that a better current inductance is obtained from tubes made of material that contains no coloring matter. The coils are wound with No. 26 gage enameled wire, which is run from a reel at the front of the lathe, and guided by the operator as shown. The tube fits over a cylindrical wooden block attached to the lathe, and the wire is passed through holes drilled in the end of the tube and is extended to permit suitable connections to be made in the circuit. This operation is performed on a Seneca Falls tool-room lathe. After the winding operation has been completed, the wire is severed and threaded through corresponding holes at the opposite end of the tube in order to anchor it.

The DeForest rheostat consists of a molded bakelite base to which a resistance coil, wound on a strip of fiber, is attached. The fiber core of the resistance coil is shown in the upper part of Fig. 3, and the special winding fixture in Fig. 2. The fiber is 1/16 inch thick by 5 9/32 inches long, and it was found necessary to employ a special fixture to prevent it from twisting and buckling during the winding operation. There are 117 turns of No. 23 B & S gage nickel-plated resistance wire wound with twenty-six right-hand turns per inch. The length of the wire is 10½ feet. The fixture used was designed by Mr. Reber, the chief toolmaker of the DeForest company.

The spindle of the lathe carries a pinion which drives, through suitable gearing, two ½-inch lead-screws having thirteen threads per inch, on which the carriage *A* of the fixture travels during the winding operation. The fiber is prevented from twisting by driving the chucks that hold both ends of the strip positively, the drive for the tail-end chuck *B* being from a pinion within the carriage, carried on the splined shaft *C*. This construction permits the pinion on shaft *C* to slide along with the carriage as the coil is being wound and to drive the chuck *B* at the same rate of speed as the chuck *D* at the head end. It will be seen that with twenty-six turns per inch and a lead-screw having thirteen threads per inch, a gearing ratio of two to one is required to give the proper rate of carriage traverse.

The fiber strip is tightened in the head-end chuck by the hollow set-screw wrench *E*. The hole in the set-screw in the chuck goes clear through, so the wire may be passed through it and through a hole in the fiber, before starting the coiling operation. Previous to this the two lead-screw nuts *F* are released by the thumb-screws which hold the two halves together, and the carriage is advanced to the head end, preparatory to starting the operation. A flat strip attached to the top of the carriage helps to support it, and carries a mark to indicate when the correct number of turns have been wound. The wire is passed over two buttons on the side of the carriage, which guide it and maintain the proper tension. When the winding is finished the operator cuts off the wire with a pair of pliers, releases the lead-screw nuts and the head-end chuck, and slides the carriage to the right far enough to remove the coil. The coil is then replaced by another fiber strip and the carriage moved to the head end. The fiber, which is now extending through the foot-

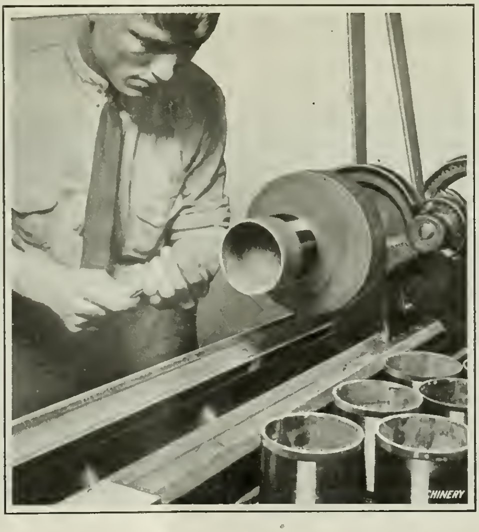

Fig. 1. Winding a Tuning Coil in a Lathe

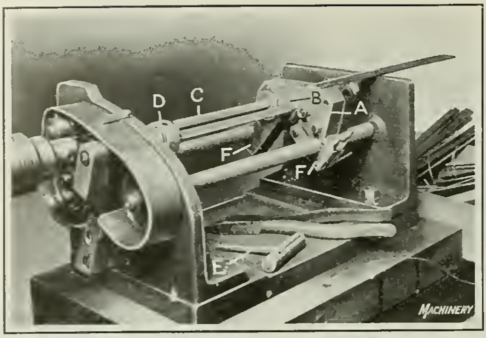

Fig. 2. Winding Fixture used on a Lathe for making Rheostat Coils

end chuck or slotted bushing on the right-hand side of the carriage, is tightened in the head-end chuck and the wire threaded through, as before.

Some Uses of Bench Lathes

The winding of variometers, which are used in regenerative circuit radio receiving sets, is done at the Adams-Morgan plant in a bench lathe. The exterior winding on the rotor member of the instrument is performed with no special means of guiding the wire other than the judgment of the operator. The interior windings of the stator member of the variometer require a special guide on the bench lathe for the wire, and this guide extends within the hollow stator, the interior surface of which is coated with shellac in which the windings are embedded. Aside from the means for reaching in to guide the wire, no other special provision is made for doing this work.

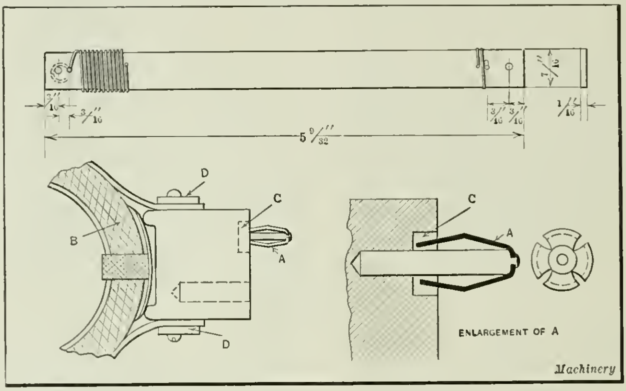

Fig. 3. (Above) Fiber Strip for Rheostat Coil Winding; (Below) Honeycomb Coil and Enlargement of its Spring Contact "Plug-in"

A number of the rotors may be seen in Fig. 4, where the operator is shown straightening the rotor shafts, with hand tools, two anvils being used to support the work. This illustration shows the character of the windings. Incidentally, attention is directed to the receiving set which is shown directly in front of the operator. The unit at the extreme right is a vario-coupler. It consists of a primary and a secondary winding, the primary coil being mounted at a 45-degree angle within the secondary, so that the windings may be variably coupled by turning the drum on which the primary coil is wound. Next to the vario-coupler is a plate condenser which, though not absolutely necessary in regenerative sets, is used to sharpen the tone. The unit at the left is a variometer; this view shows the mounting of the stator and indicates how the rotor is operated within it. The primary winding, in this case, is on the outer member, or stator.

The use of bench lathes as auxiliary equipment for finishing screw machine products is quite general in the radio manufacturing field. Indicator arms and switch points that are assembled by spinning to brass bushings molded in nonmetallic knobs, may be conveniently cleared of the burr produced in the bushing hole, by the use of a bench lathe. Small hand tapping jobs, of which there are a large variety, are also suitable bench lathe radio jobs. Other typical bench lathe work commonly found in radio shops includes smoothing the heads of brass screws with a small emery-faced wooden disk, burring and beveling shoulder screws, and countersinking holes. Fig. 5 shows a battery of Sloan & Chace bench lathes used in the DeForest plant for a wide variety of work of the class to which reference has just been made.

Lathes for Spinning Horns

Horns of various types are employed for use in connection with an amplifier, the sound being delivered from the receiver of the instrument and thrown out so as to be heard without the use of head-phones. The type of "loud speaker" manufactured by the Radio Service & Mfg. Co. is known as an "amplitron." This is not of the familiar graphaphone horn type, but is slightly different in construction from those in common use.

The "amplitron" is cone-shaped, and this cone is fastened to a suitable stand by means of which it is supported in an upright position. The open end of the horn has a flange to which three radial strips are fastened which support a cup at the center, into which an ordinary telephone receiver may be screwed. The instrument is shown on the ways of the lathe in Fig. 6. Leading from the rear of this receiver cup, there is a small horn through which the sound is carried back to the apex of the cone, where it is reflected and amplified. The wide angle of the cone is designed to eliminate distortion of sound. The cone is 10 inches in diameter and 7 inches deep, and it is made from No. 23 gage sheet copper.

Four distinct operations are required in spinning this copper cone; that is, four different spinning chucks are used. The shaping of the cone is not completed until after the third operation, when the work is annealed preparatory to the finish-spinning operation, which is shown in Fig. 6. The chuck or form

Fig. 4. Straightening the Shaft of a Variometer Rotor

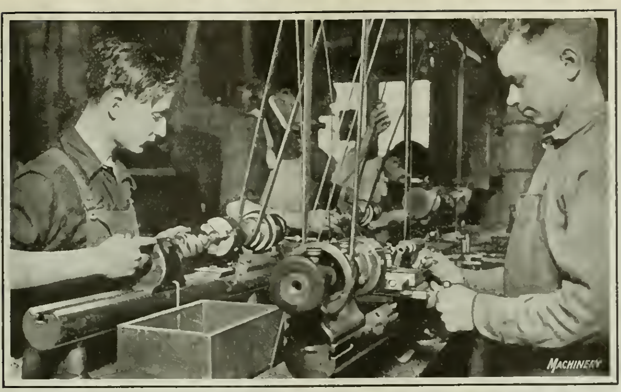

Fig. 5. Battery of Bench Lathes on which Numerous Minor Operations are performed

is made from hard maple, polished nicely, and the operation is performed on an 18-inch lathe, the tailstock of which is equipped with a ball bearing center. After greasing the wood form with albany grease, the shell is placed over it so as to run true. Four tools are used in the operation; the first has a rounded end like the bowl of a spoon, and is called a point-and-ball. This is the regular finishing tool, but it is used first to shape the apex and to work the metal back for a distance of about one inch from the apex. A small hard wood center is used between the apex

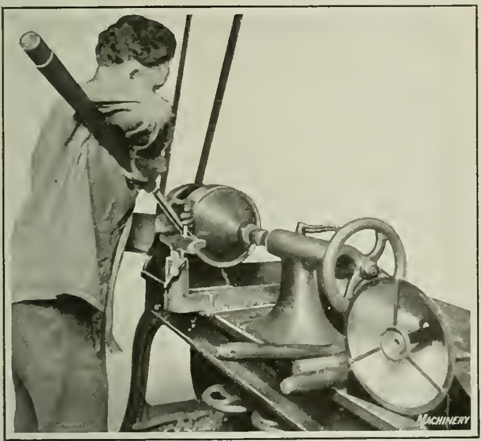

Fig. 6. Spinning a "Loud Speaker" Horn

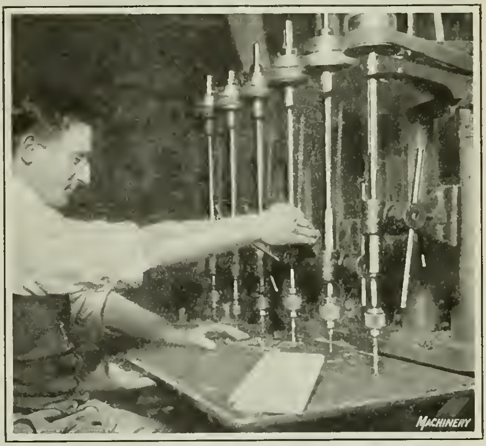

Fig. 7. Drilling Panels for Receiving Sets

and ball-bearing center during this step, but it is discarded afterward for a larger one which is employed during the remainder of the spinning operations.

The next tool is the one shown in use in the illustration; this has a blunt point on the end and a very long handle to provide the proper amount of leverage. During this operation the position of the tool on the T-rest is changed as the work progresses by transferring the fulcrum pin from hole to hole in the rest, so that the desired leverage for the tool is obtained. By the time the operator has reached the large end of the shell near the flange the diameter has increased to such an extent that he has to work in an extremely limited space, necessitating a somewhat cramped working position. This tool is brought up to the flange and across it, and then the smoothing tool is used again, this time to go over the same surfaces. Before this tool is used, the shell is greased. Lubricating the shell reduces the friction between tool and work. The corners of the flange are then trimmed with a square-edged tool, preparatory to forming the bead at the edge.

Fig. 8. Two Different Tapping Operations required on Radio Parts

In curling the edge of the flange, a pair of hook pliers is used, supported on the T-rest by a piece of wood held in one hand while the spinner uses the pliers in the other to turn the edge. The turned edge is then beaded with a tool which carries a roll at the end. After the bead has been formed, the hard wood center is removed and the smoothing tool used to finish the apex of the shell which has now been exposed by the removal of the wood plug. It will be understood that in using each of these tools any one of several holes in the T-rest may be employed for the leverage pin. to suit the convenience of the operator.

Work on Drilling and Tapping Machines

The examples of the use of drilling and tapping machines on radio work here illustrated were obtained at the plant of the DeForest Radio Telephone & Telegraph Co. The first is the drilling of thirty-three holes in the wooden panels used in the receiving sets of this company's manufacture. The panels are made of walnut and are used on crystal detector sets. They are located in a flat plate-type jig, and the operation is performed on a six-spindle Prentice drilling machine, as shown in Fig. 7. There are thirteen No. 51 drill holes, seven No. 31, four No. 27, five No. 18, two F size, and two 5/16-inch holes drilled in this sized panel.

The use of a three-spindle Allen drilling machine is shown in Fig. 9; in this view the two end spindles are being used on two different spinning operations. The contact spring *A*, Fig. 3, used in the DeForest honeycomb coil *B* and in its mounting, is assembled to a stud molded in the bakelite plugs by spinning. This operation is being performed under the first spindle, in which a roll spinning tool is used. The hole in the center of the thimble-shaped spring is slipped over a teat on the end of the stud molded in the bakelite plug, and is then secured by a spinning operation. The material surrounding the base of this stud over which the contact spring is spun, has a molded recess *C*, Fig. 3, to receive the ends of the spring and prevent them from spreading or becoming misshaped due to being repeatedly plugged into the coil mounting.

The operation being performed under the farther spindle of the machine illustrated in Fig. 9 is the spinning of brass bushings, molded in control knobs, as a means of securing phosphor-bronze indicator pointers to the knobs. The knobs are molded from bakelite, and the inserts have a shoulder at the end over which the indicator pointer seats.

The clips *D*, Fig. 3, by means of which the fiber strips are bound to the honeycomb plugs, are secured in place by machine screws, and the plugs are tapped to receive these screws on Rickert-Shafer tapping machines. This operation is shown at the left in Fig. 8. The holes have a 6–32 thread, and the material is molded condensite. The other tapping machine of the same type shown in this illustration is engaged in tapping a hole in the shanks of bakelite knobs. A wide variety of knobs of this general type are used in radio apparatus, some of which are attached by machine screws, while others are molded with inserts and have pointers assembled by spinning, as previously mentioned.

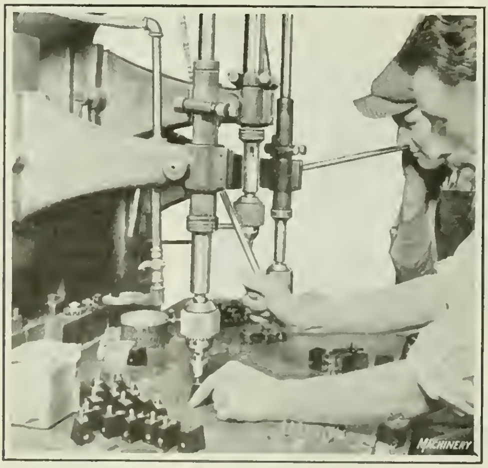

Fig. 9. Two Spindles of a Three-spindle Drilling Machine used for Spinning Operations

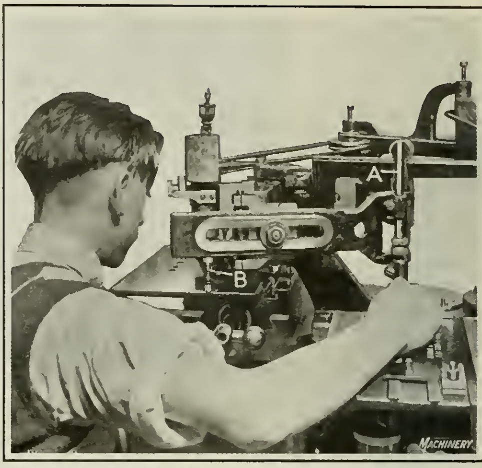

Fig. 10. Engraving Bakelite Tuner Panels on Pantograph Engraving Machine

Use of Pantograph Engraving Machines for Radio Work

Fig. 10 shows a pantograph engraving machine engaged in engraving DeForest long-wave tuner panels. These panels are sheet bakelite, and are engraved with the maker's name and various other notations regarding the type of instrument, the function of the different control knobs and switch contact points, etc. The stylus point is carried in spindle *A* and is moved by the right hand of the operator along the letters in the master plate which is attached to the table. The engraving tool is shown at *B*. The panel which is being engraved is attached to a table by clamps in the regular manner. Some of the machines used are built by the George Gorton Machine Co., and some are of German manufacture.

NATIONAL INDUSTRIAL ADVERTISING ASSOCIATION

During the annual convention of the Associated Advertising Clubs of the World held in Milwaukee June 11–15, an organization known as the National Industrial Advertising Association was formed. The following officers were elected: Keith J. Evans, Joseph T. Ryerson & Son, Chicago, president; P. C. Gunion, Hyatt Roller Bearing Co., New York City, vice-president; H. N. Baum, Celite Products Co., Chicago, secretary; A. K. Birch, Allis-Chalmers Mfg. Co., Milwaukee, treasurer. The following board of directors was elected: Julius Holl, Link-Belt Co., Chicago; L. F. Hamilton, Walworth Mfg. Co., Boston; W. A. Wolff, of the Western Electric Co., New York City; P. A. Powers, Benjamin Electric Mfg. Co., Chicago; H. J. Downs, American Locomotive Co., New York City; E. W. Clark, Clark Equipment Co., Chicago; H. L. Delander, Crane Co., Chicago; Bennett Chapple, American Rolling Mills Co., Middletown, Ohio; and J. C. McQuiston, of the Westinghouse Electric & Mfg. Co., Pittsburg.

The object of the new organization is to hold a conference in connection with every annual convention of the Associated Advertising Clubs of the World, the purpose being to gather together the leaders in industrial advertising for consideration of methods to improve the standards of advertising those products which are sold by one manufacturing plant to another. The problems involved in handling such publicity are necessarily different from those which arise in other classes of advertising. It is believed that the development of an organization for the free exchange of ideas on this subject will prove of great mutual benefit to those who participate.

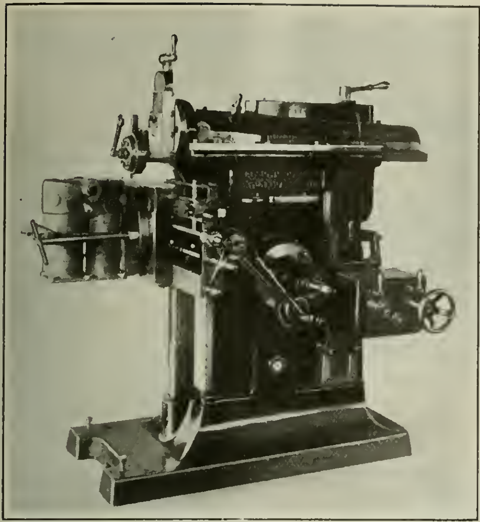

Fig. 1. Equipment used for machining the End of an Automobile Cylinder Block on a Shaper

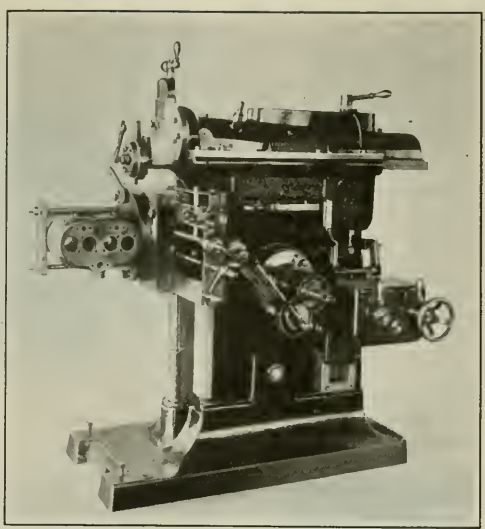

Fig. 2. Using the Equipment shown in Fig. 1 for shaping a Side of the Cylinder Block

The Shaper as a Manufacturing Machine

THERE are some classes of work on which the shaper may be used profitably as a manufacturing machine. Examples of such work are shown in this article. Most of the work illustrated was performed in the plant of the Smith & Mills Co., Cincinnati, Ohio, and all was done on shapers built by that company. Brief references only are made to the methods of performing the work, as the illustrations are self-explanatory, showing clearly both the method of holding the work and the tooling arrangement employed in each case. These examples will doubtless suggest similar applications in other plants.

Figs. 1 and 2 show a shaper engaged in machining automobile cylinders. This work was formerly done on a milling machine, but it was found more economical in this case to use a shaper, because of the saving of a double set of milling cutters. The holding fixture used on the shaper is the same as that which was formerly used on the milling machine. This is an indexing fixture, with a plunger-pin for

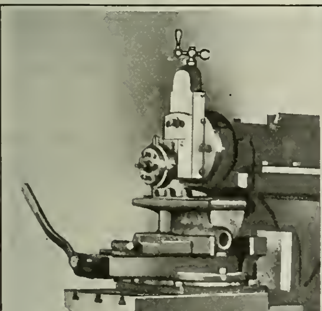

Fig. 3. Shaping the Top Casting of a Tailstock

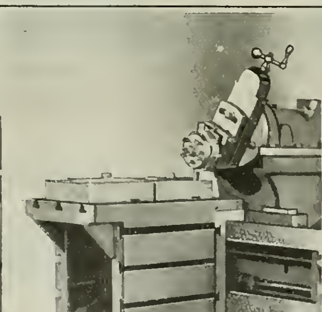

Fig. 4. Operation on a Lower Tailstock Casting

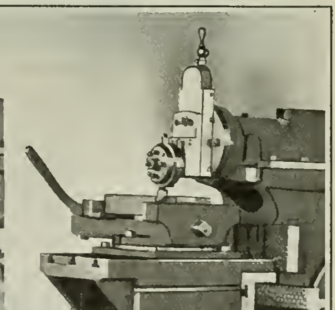

Fig. 5. Second Operation on the Part shown in Fig. 4

indexing so that the cylinder can be turned to the four positions necessary for machining both the ends and the sides of the work. The tools are held in a turret toolpost which has four positions to accommodate tools for four different operations. The cylinders are strapped to the top of the swivel plate of the fixture, so that either one of the two ends or either of the sides can be brought into position for shaping.

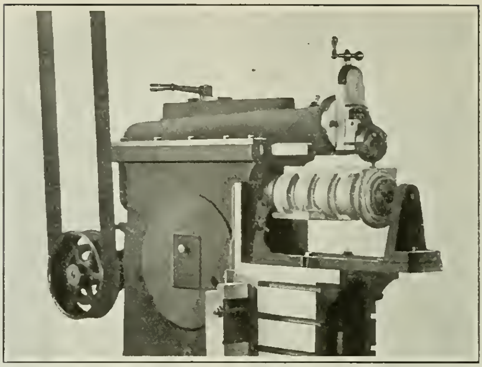

Fig. 6. Set-up for machining an Automobile Crankcase

Fig. 6 shows an automobile crankcase, which was also formerly machined on a milling machine. The job required the use of milling cutters 10 inches in diameter with inserted high-speed steel blades. It was found that this work could be done on a shaper in the same time as on a milling machine, with a saving in the first cost of tooling equipment. Furthermore, the shaper produced a straight but somewhat serrated surface which accommodated the gasket in a more satisfactory manner than the milled surface, which was wavy on account of the rota·y motion of the cutter. A turret toolpost is used in this case also, and it carries one roughing and one finishing cutter. The crankcase is machined on three sides, and the fixture can be indexed to turn the work around 90 and 180 degrees. It is clamped tightly in the fixture for the performance of the shaping operation.

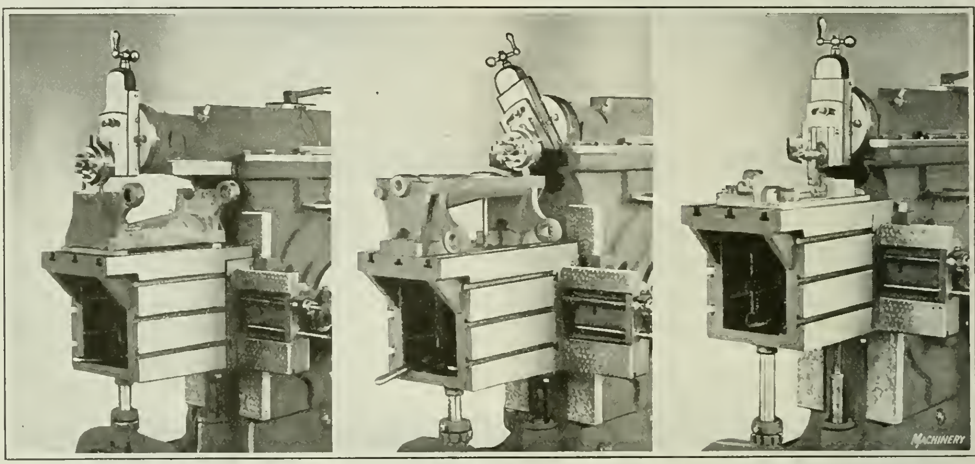

Fig. 7. First Operation on a Lathe Headstock Fig. 8. Second Operation on the Headstock Fig. 9. Trimming Bosses on Lathe Apron

Some time ago the Smith & Mills Co. had occasion to machine parts for lathes, and it was found that by rigging up shapers for planing most of the flat surfaces, the work could be done profitably at a low cost as regards both the machine tool equipment and the tools, as well as at a minimum cost for power. In the particular case under consideration, an advantage was gained by being able to machine a few parts quickly so that subsequent operations and the assembling work could be started. If, on the other hand, machine tools requiring an expensive equipment for planing a large number of these parts at a time had been used, it would have been necessary to wait longer before the subsequent operations could have been started, and while the total time consumed for each operation might have been less, the entire time consumed before some of the machines were completed would have been greater.

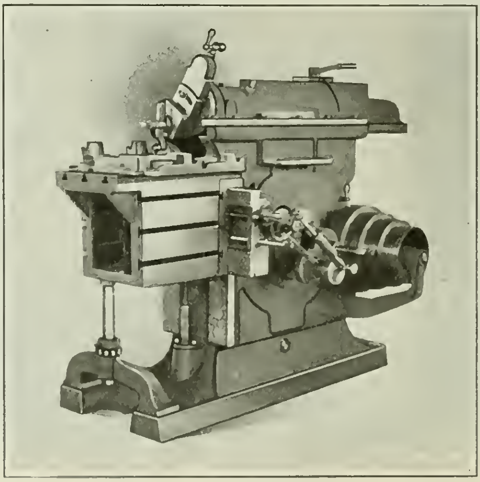

Fig. 10. Shaping out the Slot for the Split Nut on a Lathe Apron

Fig. 3 shows the top casting of the lathe tailstock being shaped on its bottom surface The casting is held in a vise and set with a surface gage, so as to insure that the hole will clean up in a subsequent boring operation, when this surface is used for locating purposes. Fig. 4 shows the lower casting of the tailstock being finished on the bottom, while Fig. 5 shows the same casting being shaped on the top. The turret toolpost is used in each instance, and is equipped with both roughing and finishing tools.

Fig. 7 shows the headstock casting mounted on the table of the shaper for the first operation. The casting is held to the table by a bolt passing through the cored hole in the center. Fig. 8 shows the

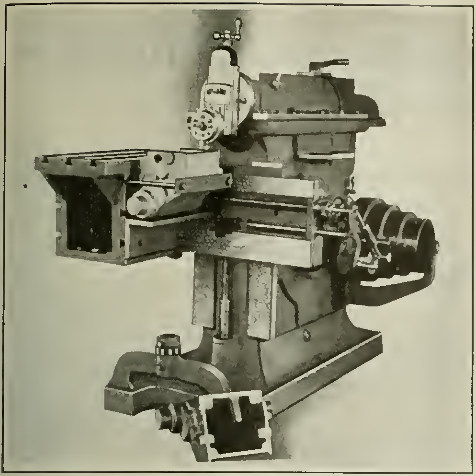

Fig. 11. Shaper equipped for machining a Lathe Feed-box

second operation—shaping off the bottom of the headstock. For this operation the work is located on setting blocks, as shown, which fit the surfaces shaped in the first operation. There is an angular way on one side and a flat surface on the other. The toolpost turret holds four tools, one for roughing and one for finishing the flat way, and one for roughing and one for finishing the angular way.

The first operation on the lathe apron is to shape off the top side and each edge. This operation is not illustrated. Fig. 9 shows the second operation, in which all the bosses are trimmed off on the inner side of the apron to an equal height, and Fig. 10 shows the shaping out of the slot for the split nut. At the end of these three shaping operations finished planed aprons were ready for further operations, such as drilling or vise work, and it was not necessary to wait until an entire lot had been finished in a multiple fixture on a planer before the work could be proceeded with.

Fig. 11 shows the lathe feed-box which was easily set up on the shaper with the use of a simple angle-plate and a strap with two bolts. In this operation the tongue and flat surfaces on the side of the feed-box by which it is attached to the lathe were machined. Four tools are used in the turret toolpost, two for roughing and two for finishing.

SHOULD FOREMEN DO DETAIL WORK?

By F. H. SWEET

The writer has known foremen who would set up every job, who would go to the tool-room and get all the tools and who would go out of their way to do various odd jobs, and yet their departments would not be efficient. They would spend so much time getting a job started right that they would have no time to superintend the work. They had no time to go over their orders, but would pick them out haphazardly or they would be picked out for them of necessity. They had no time to plan their work, to judge their men, or to watch their product, yet they would work themselves into nervous exhaustion and fail in health.

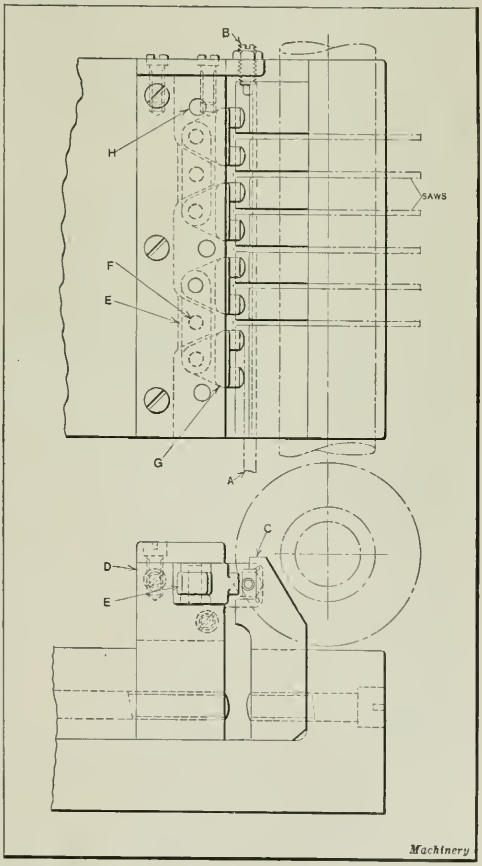
They were too busy looking after details to keep in sight the larger and more important things. They were so occupied that they had no time for conferences or interviews. They fooled themselves into thinking that the details they were doing could not possibly be done by anyone else. "One of the hardest things I have had to learn, is when to cease doing a detail and delegate it to someone," said one manager. This is especially difficult when it involves things that one can do very well, or things that one likes to do.

FIXTURE FOR MULTIPLE CUTTING OFF

By D. A. NEVIN

In the manufacture of firearms, typewriters, adding machines, and various classes of light machinery, there are many small parts that must be made from pieces sawed off from flat bar stock, because the thickness is too great to permit blanking them from flat sheet metal. In many cases the material is hard steel, which makes it difficult to obtain satisfactory results by cutting off in an automatic screw machine. For this reason these parts are often cut off in a milling machine, using a standard manufacturing vise to hold the stock. The illustration shows a pair of special vise jaws which were designed for use in sawing off six parts simultaneously, by employing six gang saws mounted on a milling machine spindle. The stock was $\frac{3}{8}$-inch by $\frac{1}{4}$-inch hard steel and is shown by dot-and-dash lines at *A*. The work is located against an adjustable stop-screw *B*, which is secured by a lock-nut. The saws are 1/16 inch thick.

The stock is supported by the rigid jaw *C* and clamped by the movable jaw *D* fitted with compound equalizers which provide for clamping all parts rigidly in place, thus allowing a maximum feed of the saws. The equalizing parts consist of the links *E* retained in the slotted jaw *D* by the pins *F* and carrying on each end the equalizing clamps *G*. Three pins *H* are provided to prevent the equalizing clamps from getting out of position. The parts are cut to a length of 0.494 inch plus or minus 0.0002 inch, and the jaws are mounted in a No. 3 Brown & Sharpe vise.



Vise Jaws for Multiple Cutting-off Operations

Cost Recording and Production Control in Drop-forging Plants

Fig. 4. Sheet on which a Record is kept of the Stock on Hand

In the first installment of this article, published in June MACHINERY, the general need for more efficient cost-recording systems was emphasized, and some of the difficulties encountered in developing cost-recording systems in drop-forging plants were dealt with. Following this consideration of the cost-recording problem, an outline of a system of management which has proved very satisfactory in two large drop-forging plants was given. In the present installment the actual operation of the system will be described in detail.

In order to make clear the operation of the system, the progress of an order will be followed from the time that it is received by the sales department until the finished forgings are shipped. When an order is received by the sales department a set of sales orders is immediately made out on blank forms like that shown in Fig. 7. This order gives all the information available that will be of assistance to the executives who are responsible for the proper execution of the work. It will be noted that all items required in figuring costs are included on this order slip, so that there should be no cause for error or delay in obtaining the costs. A copy of this order is sent to the cost, the billing, and the production departments.

the production department, the information board is consulted to determine the condition of the dies and trimmers. If a new die is required, an order is made out on a form, the front and back of which are shown in Fig. 5. If the die simply requires repairing, an order is made out on a form provided for that purpose. These orders give all the information required, including the time allowed. Copies of these orders go to the die-room and cost department.

Ordering Materials

From the steel or stock record, made out on the form shown in Fig. 4, it is next ascertained if the steel required in making the forgings is available. If the stock is on hand, the allotment of the required amount is noted on the record, and a requisition is sent to the purchasing department, calling for an amount of steel sufficient to replace the allotment. This requisition is made out on the form shown in Fig. 8. If the record sheet shows that the steel is not available, the same procedure is followed so that all the records will be complete and up-to date. Complete information in regard to the quality and kind of steel needed is placed on the requisition slip.

When the purchasing department orders the steel, a copy of the order is sent to the production department, which then follows the order until shipment is made. All information regarding the ordering of steel, the condition of dies, etc., is posted on the information board by inserting tacks of the proper shape, color, or color combination. For instance, referring to Fig. 2 in the first installment of this article, the tack at *d*, which is black with a white cross in the center, indicates that the steel is available and an allotment has been made. A triangular green tack *e* shows that the trimme:s have been inspected and found ready for use. A square red tack at *f* shows that the lead cast of the forging has been approved, and a square green tack at *g* indicates that the dies are ready for use.

CUSTOMERS SCHEDULE and REMARKS

Fig. 7. Sales Order Blank, which is filled out by the Sales Department

The system for receiving and inspecting the stock is as outlined in the following: At the time an order of steel is received, a receiving and analysis card, the front and back of which are shown in Fig. 6, is made out in the production department. When a shipping manifest of steel is received by the production department, a lot number is assigned to every size according to its specifications. If more than one heat of each size is included in the order, a letter is added to the lot number, and in unloading, care is taken to see that each size and lot are placed in separate piles and properly marked. Two copies of the receiving and analysis card are sent to the yardmaster, one copy to the inspection department, and one to the laboratory. When the car carrying the steel arrives, the yardmaster notifies the inspection department by sending it one of the copies of the steel receiving and analysis card, after which he weighs the car.

Fig. 8. Requisition sent to the Purchasing Department

The inspection department makes a surface inspection of the steel, and takes one sample, by lot numbers, from each ten bars for analysis. Then there is placed on each lot the inspectors "hold card" on which is printed in large type "Hold—do not use this material. It has not been passed by the inspection department." The samples are next sent with the yardmaster's notification slip to the laboratory. The steel is inspected during the unloading operation, at the end of which the car is weighed light, and the weight entered on the receiving and analysis card, as shown in Fig. 6.

When the steel analysis has been completed at the laboratory, the inspection

analysis slip is sent from that department to the inspection department and the "hold card" is removed from the steel. This steel is then available, and the inspection analysis slip is sent to the production department. At the time the car is unloaded, the yardmaster sends his second copy of the receiving analysis slip to the purchasing department, as a receiving slip. Each step in the receiving, testing, and storing of the steel is recorded on the information board.

Approval of Lead Cast

As soon as the lead cast is ready for the customer's approval, the die-room forwards it to the inspection department. After it has been approved by the inspectors, it is sent to the production department, and from there to the customer. When the customer approves the lead cast, the production department makes out a set of lead cast approval slips on the form Fig. 9. Three copies of this approval slip are sent to the die-room and one to the billing department. When the dies and trimmers are ready for use, the die-room forwards one copy to the production department and one to the cost department. This progress is also posted on the information board.

Delivery of Steel at Forging Hammer

About five hours before a hammer completes the job on which it is at work, the production department makes out a set of release slips of the form shown in Fig. 10. Copies of this slip are sent to the die-room foreman, hammer-shop foreman, steel-room foreman, timekeeper, and cost department. When the steel-room foreman receives his copy, he immediately prepares to transfer the steel from the store-room to the hammer, so that no delay will occur.

Fig. 14. Daily Production Report Sheet made out from the Individual Hammer Reports

When the steel-room foreman delivers the steel to the hammer he makes out a steel delivery slip on the form shown in Fig. 12, and if at any time he removes steel from the hammer he makes out a transfer slip on the form shown in Fig. 13. At the close of each shift, one copy each of these slips is handed to the production and cost departments. The steel-room foreman has the amount of steel at the hammers checked at the beginning and end of each shift, and the amounts recorded on the slips. The production department then checks the amounts on these slips against the forgings made, and deducts from or adds to the steel record the amounts shown on these slips.

As work on the order progresses, the floor inspector makes out at the end of each shift an individual hammer report on the form shown at *A* in Fig. 11. These reports are sent to the production department at the end of each shift. As these slips give the amount of steel for each hammer at the beginning and close of each shift, the number of net rejects and scrap forgings made, the number of productive hours spent, and the reasons for any delay or

failure to meet the production schedule, it is an easy matter for the production department to record all progress on the production board.

From these slips and the shipping report, the production department makes out the daily production report on the form shown in Fig. 14. The production record is made out from this production report on the form shown in Fig. 15. If the floor inspectors find defective forgings that can be repaired, they place a defective ticket such as shown at *B*, Fig. 11, on them, and send the stub or lower part of the ticket to the production department with the individual hammer reports. When the pieces are repaired and passed by the inspector, the remainder of the ticket is turned in to the production department also. Whenever forgings are moved from one place to another for different operations, a "move ticket," such as shown at *C*, is made out.

Fig. 17. Shipping Order Blank

When a job is completed, the dies are removed from the hammer and sent at once to the die-room. The hammer-shop foreman fills in the remainder of the release order and sends it to the production department. Upon receipt of the dies and trimmers, the die foreman makes out an inspection report on the form shown in Fig. 16, and sends it to the production department. This information is recorded on the information board.

Shipping Statements

When a hammer release slip is made out by the production department, a set of shipping statements are made out on the form shown in Fig. 17. One copy of these statements is kept as a tracer, one forwarded to the billing department, also as a tracer, and four copies are sent to the shipping department. Two of the copies are sent to the shipping department when the goods are shipped to the customer, one to be signed by the customer and returned, and one to be retained by him. One copy goes directly to the cost department and the other to the production department. From the copy received by the production department is posted the production record, after which this copy is sent to the billing department from which it is sent to the cost department. At the end of each day the shipping department sends one copy each of the daily shipment reports, Fig. 18, to the production, billing, and cost departments.

When shipping instructions are given to a customer for the return of goods, the production department makes out a set of receiving inspection reports on the form shown in Fig. 19, and sends them to the receiving department. When the forgings arrive, this set of reports is sent to the inspection department, where the goods are inspected. Three copies of the inspection report are then sent to the production department, which, in turn, forwards one copy to the billing department and one to the cost department. The inspection department attaches a ticket to these forgings like the one used for shop rejects, and from then on they are handled in the same manner as shop rejects, except that they bear a repair order number instead of a sales order number.

A system such as the one described in the two installments of this article makes it possible for an effective control to be exercised over production in a drop-forging plant and for an accurate record to be kept of the costs of production, which, of course, are vital requirements in any manufacturing organization. The various forms illustrated will be of suggestive value to other plants engaged on the same or similar classes of work, who wish to install a system that will enable them to determine definitely whether their work is being done at the lowest possible cost. These forms would, of course, be modified to suit the conditions peculiar to different plants.

* * *

According to *Safety Engineering*, 75,500 lives were lost and 2,000,000 people seriously injured in the United States by accidents last year. Of this number 11,000 persons were killed in automobile accidents alone.

HELPING EMPLOYES TO SAVE

At the plant of the Dodge Mfg. Co. in Mishawaka, Ind., it was realized some years ago that the failure of employes to save any part of their wages was preventing them from getting the success and satisfaction out of life that their work and efforts entitled them to. Not that conditions were any worse in this factory than elsewhere; it was simply that the management of this concern noted an obstacle in the path of men in the company's employ. The fact was borne home with unusual strength during the early part of 1915 when industrial wages were reaching a new high level.

At that time C. E. Lukenbach, employment manager of the Dodge Mfg. Co., came before the directors of the firm with a plan designed to instruct employes in the practice of thrift. He claimed that factory workers could be taught to save a definite amount of their weekly wages, and offered to interview the men in the factory personally and get them to join a Thrift Club. According to the plan, no inducement was to be offered beyond that of calling attention to the failing common to all classes of men of spending their entire income.

The preliminary canvass for members of the Dodge Thrift Club was started in May, 1915, and during the first week pledges of weekly deposits were received amounting to $79.50. Every man had to be "sold" personally on this proposition; but the results are shown by the fact that from May, 1915, to January, 1916—a period of seven months—the deposits had increased to $6000, and on January 1, 1917, this amount had grown to $20,000. From that time on the progress of this Thrift Club has been almost phenomenal. During 1919 the amount deposited was $82,000, and for 1920 the deposits totaled $130,000.

In order to bring the benefits of the Thrift Club within the reach of all factory employes, it was decided to accept deposits in amounts of 25 cents a week up, in any multiple of the minimum deposit. All those who join the Thrift Club are expected to continue making deposits for at least thirteen weeks, and after twenty-six weeks, interest is paid on the average balance at the rate of 5 per cent. Every depositor is urged to start low and to increase his rate of deposit as he is able to. At the present time deposits range from 25 cents up to $30 a week. There are three men who deposit their entire wages and then take advantage of the checking privilege which goes with membership in the club. A depositor may withdraw any sum on such checks up to the amount of his entire deposit. To do so he goes to the office and fills in a special withdrawal notice. This notice is sent to the treasurer's office, and a bank check is drawn against the account of the Thrift Club in favor of the member who wishes a check for the payment of some current bill.

The measure of success of this Thrift Club is best shown by the fact that many men who formerly spent every cent they earned have now formed a habit of setting aside something for the proverbial "rainy day." At the time the club was started many of the men had been in debt for years—not, perhaps, for a large amount, but nevertheless in debt.

To show the results that the Thrift Club is accomplishing, it will be of interest to cite one or two specific examples. Not long ago a man came to the office of the employment manager and asked for a blank on which he ordered the withdrawal of $21 from his account in the Thrift Club. That man's wife had been sick and the rent money had been used to pay the doctor. It certainly made things easier to have a surplus for the landlord on the first of the month. Another man who had been most difficult to get into the Thrift Club accumulated a surplus of $86, and then used the money to clear up a number of debts; he stated that during fourteen years of married life he had never been out of debt.

Insurance Privileges of the Mutual Relief Association

In addition to the Thrift Club, the Dodge Mutual Relief Association maintains a fund from which payments are made to the members for time lost through sickness and also to the beneficiary of the insured upon death. There are six different plans of insurance to which subscription may be made, and these carry various benefits for disability or death. At present there are 750 members of the office and shop force who are carrying this protection, and as it is obtained on the mutual basis, that is, without yielding any profit to stock-holders, the rate is very low.

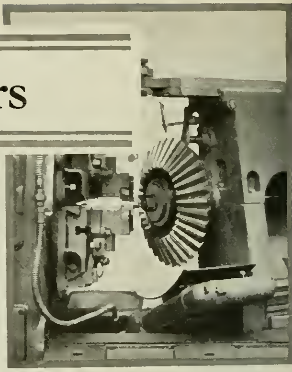
Cutting Bevel Gears



Principles Governing Operation of Generating Planers and General Methods of Setting up and Adjusting Bilgram Machine for Cutting Bevel Gears—First Installment

By FRANKLIN D. JONES

CUTTING bevel gears is not so simple as cutting spur gears, because the teeth have a converging form. A correctly formed bevel gear tooth has the same sectional shape throughout its length but on a diminishing scale from the large to the small end. This accounts for the fact that a bevel gear cannot be cut properly by using a formed milling cutter which simply reproduces its shape, because if this cutter were of the exact curvature required at the large end of the tooth, it would not be correct for any other part, and the error would be considerable at the small end of the tooth. Consequently, accurate bevel gears are cut by a generating process, since that is the only way to give the tooth the proper curvature on a diminishing scale, the tooth tapering toward the apex of its pitch cone.

Principle of Generating Process as Applied to Bevel Gears

In connection with the cutting of spur gears by generating methods, it was explained that the straight-sided rack of involute gearing is represented either directly by the cutter used, or indirectly as when a circular form of cutter is generated from the rack. Now the relation between a rack and spur gear is similar to that of a crown gear to a bevel gear; thus the pitch surface of a rack and also of a crown gear coincides with a plane. The teeth of a crown gear are also straight sided like those of a rack, although of converging form, and the inclination of each side corresponds to the pressure angle. The cutting tools of bevel gear generators, therefore, represent the crown gear and when a bevel gear is being cut the tooth curves are derived by imparting to the work and to the cutting tool the same relative motion that would be obtained if the gear being cut were rotating in mesh with the crown gear. In addition to this generating motion, provision must be made in a practical design of machine for giving the tool or tools a reciprocating motion for cutting, and an indexing movement to the work in order to cut equally spaced teeth around the entire gear.

The generating motion on some machines is obtained by rolling the gear being cut, relative to the cutting tool (representing a crown gear tooth) just as though this gear were finished and rolling around a stationary crown gear. Thus all the generating motion is applied to the work; the cutting tool is simply given a reciprocating motion for planing. This method of generating is illustrated by the diagram Fig. 1. The gear to be cut, which is usually roughed out before finishing the teeth on a generator, is rolled about axis x of an imaginary crown gear while the planing tool is at work. One side of this tool or cutter is in the same position as the side of a crown gear tooth, and the point of the cutter moves along line x—y. The cutter forms one side of the tooth while the gear is slowly rolling from the position indicated by the full lines to the position shown by the dotted lines.

This rolling motion must be sufficient to roll the entire side of a tooth along the straight cutting edge of the tool. This straight cutting edge produces a smooth curved surface, because the rolling movement is very slight for each cutter stroke; hence, a number of strokes are required to finish the side of a tooth. Means must be provided to positively and accurately control this rolling motion of the gear. Suppose that the work-spindle carried at the outer end a master gear or a segment gear extending over a large enough arc to provide for all the rolling motion that is required; and assume that this master gear segment has the same pitch cone angle and pitch as the gear to be cut and is in mesh with a fixed crown gear segment. Then the rolling action can be properly controlled. The Bilgram machine, which is one type to be considered, operates on this general principle, although instead of actually using master and crown gear segments having teeth, a segment of the pitch cone with a smooth conical sur-

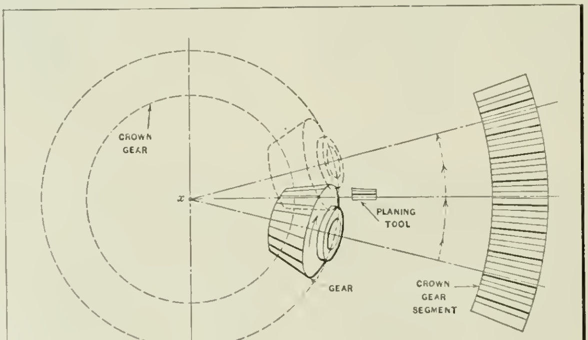


Fig. 1. Diagram illustrating Action of Bevel Gear Generator when all of the Generating Motion is applied to the Gear

face rolls on a flat surface as explained later. In the diagram Fig. 1, no provision is made for indexing the gear to present different teeth to the cutting tool. This part of the mechanism will be considered in connection with commercial types of machines.

Action when Generating Motion is Applied to Both Gear and Planing Tool

A common type of bevel gear generator is so designed that the generating action is applied to both the work and to the cutting tools. In this case the action is similar to that of a crown gear rotating in mesh with the gear being cut, each gear revolving about a fixed axis. Fig. 2 represents this generating motion in diagrammatic form. While each gear tooth is being planed, the gear turns part of a revolution about a fixed axis x—x, just as though the imaginary crown gear were turning with it. The planing tool also swings around with the gear as though it were one of the crown gear teeth. Only one tool is shown on the diagram to simplify it, although two are used on the Gleason machines which represent a commercial application of the generating motion illustrated by this diagram. Because of the converging form of the space between two teeth, it is impossible to cut more than one side at a time with a single tool or cutting edge, although it is not only feasible but desirable to use two tools which operate on both sides of a tooth.

On some machines the generating action indicated by Fig. 2 is controlled by a crown gear, which, as indicated by the diagram, swings with the toolslide, and is in mesh with a master gear segment connecting with the work-spindle. Such an arrangement causes the crown gear segment and the tools to move through an arc represented by the full and dotted lines, while at the same time the master gear rolls in mesh with the crown gear and causes the gear blank to turn in unison with the tools. Another method of regulating and controlling this generating motion is by using suitable combinations of change-gears instead of the crown and master gear segments. Thus, by selecting gearing of the proper ratio, the relative motion between the tools and work is the same as though a crown and master gear segment were employed.

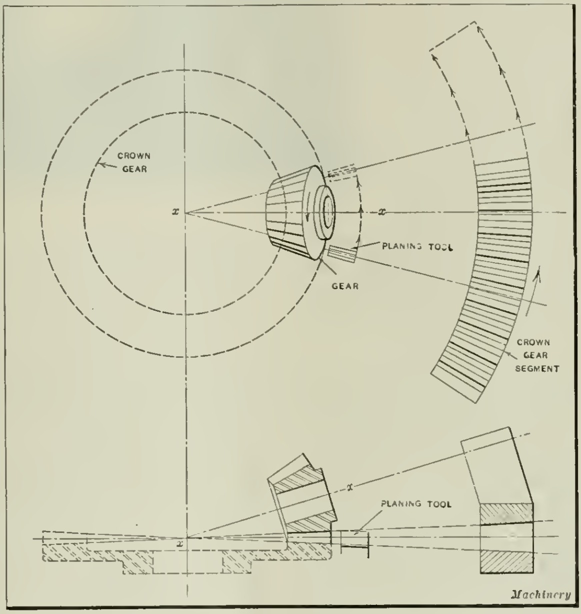

Fig. 2. Diagram representing Action when Generating Motion is applied to Both Gear and Tool

Planing Bevel Gears on Bilgram Machines

The Bilgram bevel gear generator made by the Bilgram Machine Works, Philadelphia, Pa., operates on the principle illustrated by the diagram Fig. 1, of imparting to the gear to be cut, a rolling motion corresponding to the rotation of a finished gear rolling on a crown gear. This generating motion might be derived from a master gear rolling on a crown gear as previously explained, but in the practical application of this principle to the Bilgram machine, a segment of the pitch cone is used instead of a master gear, and as this segment rolls on a flat surface representing the pitch surface of the crown gear, the blank being cut receives the required generating motion.

The action of this machine and its adjustment for cutting bevel gears will be described in connection with Figs. 3 and 4. While these views are not of the same machine, they show the mechanism from opposite sides. The part of the machine to the right, as seen in Fig. 3, is the shaper or planing mechanism, and at the left of the gear being cut is the generating mechanism from which the rolling motion is derived. When the machine is at work, the tool is lifted to clear the blank during the return stroke, but it does not have a lateral feeding motion like the Bilgram spur and spiral gear generator. During each return stroke of the tool, the gear blank indexes to bring the following tooth space into the cutting position. In conjunction with this indexing movement the progressive rolling action of the gear occurs. The vertical axis of the imaginary crown gear about which the gear being cut rolls, is at the left of this gear, and the action of the gear is the same as though it were rolling on a crown gear having teeth on the under side.

The planing tool (representing a crown gear tooth) takes successive cuts from tooth spaces around the entire gear as the latter is indexed after each cutting stroke; consequently, when rough-planing a gear from the solid blank, all of the teeth are roughed out while the gear is slowly rolled from the beginning to the end of its generating movement. When finishing a gear after roughing, all of the teeth are first finished on one side and then, after making a slight adjustment and inserting another tool, the remaining sides of the teeth are formed.

The cutting of gears directly from solid blanks is common practice in connection with jobbing work; if a quantity of duplicate gears is required, the teeth may be roughed out on another type of machine adapted for this work and the generator used only for finishing. The stroke of the tool is regulated by an adjustable crank, and the means for automatically lifting the tool during the return stroke is part of the shaper mechanism.

Operation of the Spacing and Generating Mechanism

The mechanism which serves to index the gear and impart a rolling motion to it is connected with the driving end of the machine by two shafts A and B, Fig. 4. The motion for indexing or spacing is derived from shaft A, which is splined and drives through spiral gears so arranged as to permit the generating head to move in any direction. The indexing mechanism has an intermittent or Geneva wheel motion and change-gears which are in action during the return stroke of the tool. When the tool is cutting, a pawl engages a spacing wheel which is so located as to insure accurate indexing, irrespective of lost motion in the change-gears.

The rolling motion is derived from shaft B, which is revolved at whatever speed is required to obtain a suitable rate of feed, depending upon the pitch, number of teeth, and material to be cut. A circular design of geared feed-box is located at the left-hand end of shaft B, beyond the range of this particular illustration. The cross-shaft C, driven by B, carries a worm which meshes with a worm-wheel segment attached to the base connecting with the main work-spindle. The vertical axis of this worm-wheel segment coincides with the axis of the imaginary crown gear previously referred to and represented by axis x in Fig. 1. The cone segment D corresponds, at least approximately, to the pitch cone angle of the gear to be cut, and rolls on a horizontal surface as the worm-wheel segment turns slowly about its vertical axis. This cone segment is attached to segment-shaped bars E by clamps at F, the latter providing means of adjustment according to the angle at which the work-spindle is set. (The arrangement of the cone segment and supporting bars is shown more clearly in Fig. 3, as the machine happens to be equipped with a cone segment of larger radius.)

The rolling motion is controlled by two steel bands G, Fig. 4, which are attached at one end to the cone segment and at the other end to the horizontal bar. With this arrangement, when the worm on shaft C revolves the worm-wheel segment, the cone segment D rolls along on its horizontal surface, representing the pitch surface of the crown gear; consequently, the work-spindle has a rotary motion about its axis, and at the same time swings bodily about the axis of the imaginary crown gear. The result is that the gear being cut is given a correct generating motion relative to the planing tool. The machine is equipped with a series of cone segments of different angles which are selected in accordance with the pitch cone angle of the gear that is to be cut.

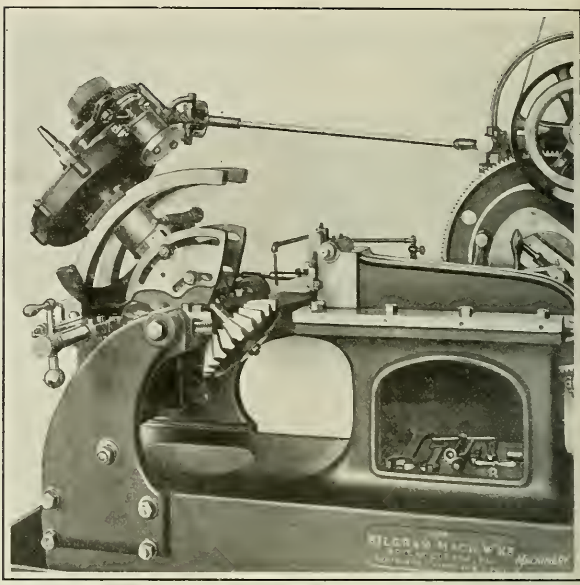

Fig. 3. Bilgram Bevel Gear Generator

General Method of Adjusting the Machine

When setting up a machine, the work-spindle is first adjusted according to the pitch cone angle of the gear to be cut. The segment and worm for making this adjustment are shown at H, Fig. 4. A pitch cone segment is selected which is nearest to the pitch cone angle of the gear. If the latter angle is about midway between two segment angles, preference is given to the smaller angle. The pitch cone segment is attached to bars E, as mentioned previously, and steel bands leading from each end of the segment to opposite ends of the horizontal "cone bar" are attached and stretched moderately tight. The change-gears and anchor wheel of the indexing mechanism are selected according to the number of teeth in the gear. These change-gears are located at N on the outside of the spacer housing.

As the planing tool must travel parallel with the bottom of the tooth space, it is necessary to make an adjustment equal to the dedendum angle. This is done by adjusting the entire generating mechanism, which is supported on each side by trunnions J. A screw connected with handwheel K is used, and the angle of adjustment is determined by graduations on scale L in conjunction with graduations on a bevel surface of the handwheel.

When the blank is properly set, the apex of its pitch cone coincides with the axis of trunnions J of the generating mechanism, which axis also intersects the vertical axis of the imaginary crown gear. The gear to be cut is adjusted axially, or in the direction of the work spindle, in order to locate the apex of the pitch cone in the right position. Small gears may be clamped to a mandrel which is adjusted longitudinally, but larger gears should be clamped against the lower end of the spindle with bushings between to get the proper adjustment. While adjustable collars may be used, solid collars faced to the required thickness are preferred. After the gear blank is clamped, its location is checked by a height gage set to the height of the tooth. Thus the gear blank is raised or lowered until this gage, when turned down into contact with the edge of the blank, gives a reading equal to the required tooth height. The accuracy of the blank is then checked by allowing the blank to make about one-quarter turn and repeating the height gage test three times.

As a final check, a distance piece, in conjunction with a gage bar of the machine, is used to determine the apex distance of the gear. While this measurement is being made, the generator should be in its central or zero position as regards the feeding motion. While the apex distance, to be strictly correct, should be measured when the generator is set horizontally or with the addendum

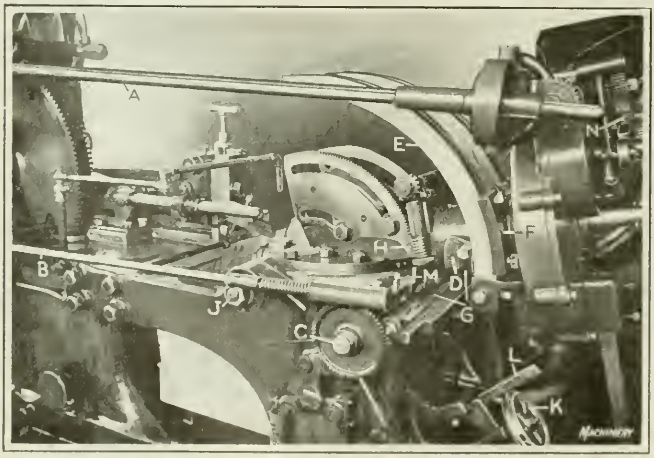

Fig. 4. Detail View of Another Bilgram Generator

angle at zero, this discrepancy can do no harm if the apex distance actually measured is noted and the mating gear is afterward set to the same distance.

Tools Used on the Bilgram Machine

There are three tools in a set. One is for stocking out, and there are right- and left-hand side-cutting tools for finishing opposite sides of the teeth. These tools may be ground on a surface grinder by using a holder supplied for this purpose. When a gear is to be roughed out on a machine, the stocking tool is set in a central position. A mark on the tool-slide shows when the tool is in the center. Thin packing strips are used with the smaller 6-inch machine. When using the side-finishing tools, the tool is set so that

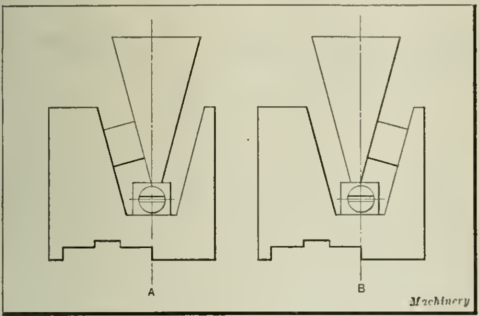

Fig. 5. Diagram showing Method of setting Tools on Bilgram Generator

the point or corner of the cutting edge is in the central position, as illustrated in Fig. 5, which shows the right- and left-hand tools.

Only one side of the teeth can be generated at a time, because of the forging form of the tooth spaces. The finishing tool must be set so that the lowest point of the cutting edge moves in a direct line toward the apex of the pitch cone or the center of the generator. The proper adjustments are obtained by a tool gage and gage-block illustrated in Fig. 5. The side-cutting tools have side slope or rake to give a better cutting action, whereas the stocking out tool is ground square across the end. When cutting some gears, such as soft bronze, for example, the tools with side rake may tend to gouge into the teeth and then the stocking out tool may be used for the side finishing cuts. When taking these finishing cuts, the lower edge of the tool should clear the bottom of the tooth space, as such contact sometimes causes chattering.

Angular Adjustment of Blank to Obtain Convergent Form of Tooth Space

The opposite sides of tooth spaces must be cut at slightly different angles, because both sides converge toward a common apex. For this reason, after the teeth are finished on one side, the gear is given an angular adjustment called the "shift." The master pinion engaging the master indexing or spacing gear, is so held that its position can be changed independently of the anchor wheel and change-gears. This movement is measured by a vernier scale. It is advisable to set the scale at zero when stocking out gears, and when finishing the sides of the teeth one-half of the amount of shift prescribed on the blueprint or shop order should be allowed on each side of the zero position. It is not necessary that the total shift be divided into equal parts, so long as this total amount is obtained when shifting from one side of the teeth to the other.

The feeding mechanism through which shaft *B* Fig. 4 is rotated, is set, not only with reference to the pitch of the teeth and the material, but also for roughing and finishing cuts. Thus, for finishing, a considerably higher rate is usually permissible than for roughing cuts. The feed may also be increased when stocking out, during the time the tool is approaching and after it has passed the middle position where the cutting is heaviest. Provision is made for reversing the direction of this feeding motion. The stop-pin *M* is placed on one side or the other according to the direction of feed, and fixed stops are also provided to insure stopping the machine if the operator should neglect to insert the adjustable stop-pin.

General Method of Operating Machine

After all adjustments have been made, the generating head is moved by hand for locating the blank in the proper position preparatory to starting the cut. The handle used for this adjustment is on the opposite end of feed-screw *C* (see Figs. 3 and 4). The feed mechanism is disengaged for this hand adjustment by loosening a knob in the front of the handle. The blank is first rolled away from the operator far enough for the tool to clear it; then, after starting the machine, the blank is brought back to a point where the tool begins to cut. Then the automatic feed is engaged. The direction of the feeding movement is controlled by a reversing knob on the feed box. The shift vernier should be set at zero for the stocking out cut, assuming that the gear is roughed out on the same machine used for finishing.

The first finishing cut is taken with that tool which cuts on the side farthest from the operator. This is the right-hand tool, and it is set so that the lower corner is in the central position as shown at *A*, Fig. 5. The shift vernier which has plus and minus graduations, is set on the plus side an amount equal to one-half of the shift required. After the blank has again been rolled away from the operator by the hand adjustment, and the geared feed-box is set for a coarser feeding movement, the finishing cut on one side of the teeth is taken. This cut is sometimes repeated to eliminate any inaccuracies due to springing action. Before taking the finishing cut with a left-hand tool, the shift vernier is set by the minus scale to one-half the shift required, and the feeding motion is reversed.

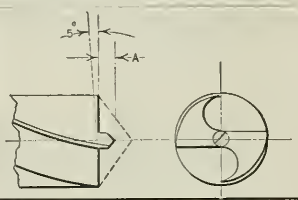
DRILL DIMENSIONS FOR TIN-PLATE DRILLING

By A. A. MARGIN

Holes larger than 5/16 inch in diameter cannot be drilled satisfactorily in tin plate with drills ground in the usual way. Even when a small lead-drill is used first and then followed up with a larger drill, the hole produced is likely to be over size, out of round, off center, and in some instances badly shattered. These defects may also result from the use of a combination centering drill.

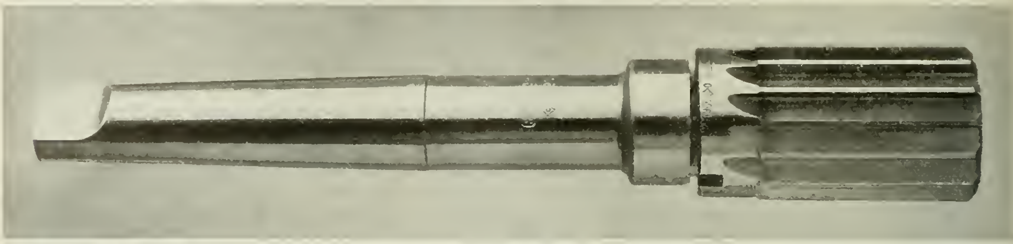
The writer has found that such difficulties may be avoided by grinding the drills in accordance with the data given in

Size of Drill, Inches	Dimension A, Inch
5/16 to 5/8	1/8
5/8 to 1 1/8	3/16
Over 1 1/8	1/4



the accompanying table. This table has been used to advantage in the tool-room when drilling tin-plate templets for laying out purposes. This work frequently requires the drilling of a large number of holes of different sizes, each of which must be round and accurately positioned.

A good example of the kind of work for which these specially ground drills proved satisfactory was a 12- by 12-inch plate, 1/16 inch thick, requiring ten accurately spaced holes ranging in size from 5/16 to 1½ inches in diameter.



Standardizing Shell Reamers and Arbors

Standard Dimensions Governing the Fits, and Gages Used for Inspection

By H. S. KARTSHER, Mechanical Engineer, The Cleveland Twist Drill Co., Cleveland, Ohio

CONSIDERABLE trouble has been experienced in the past with shell reamers and shell drills not fitting properly on the arbors used for driving them. This was due to the fact that different manufacturers had their own standards, and not more than two or three of the dozens were alike. Consequently, the reamers bought from one manufacturer would not fit the arbors of another. To eliminate this difficulty, the Drill and Reamer Association has specified that the reamer holes be made to a taper of ⅛ inch per foot on the diameter, that the arbors be tapered to correspond, and that the driving slots in the end of reamers and the lugs on arbors be made in accordance with the dimensions given in Table 1.

The various letters in this table refer to the dimensions indicated by the same reference letters in Fig. 1, where the taper of the arbor and reamer hole is shown considerably exaggerated for the sake of clearness. All tools made to these dimensions are to be stamped with a block letter S to distinguish them from tools made to old standards. The Cleveland Twist Drill Co. has set certain allowances and tolerances on these dimensions, and in the following a resumé of these fits will be given, together with a description of the gages used for inspecting the tools to see that they are machined to the correct size. It is only by adhering to a uniform system of tolerances in gaging of this kind that true interchangeability and satisfactory service to customers can be obtained.

Allowances and Tolerances for Fits on Taper Surfaces

In order to insure a good fit on the taper surfaces, an allowance *E*, Fig. 1, is made between the face of the reamer, when seated on the arbor, and the face of the arbor collar. Tolerances are placed on the large diameter of the hole in the reamer and on the diameter of the arbor (disregarding the recess near the collar) at a point located a distance *E* from the collar face, the basic diameter given for *H* being the minimum diameter in the case of the reamer, and the maximum in the case of the arbor. These tolerances are expressed in terms of length with respect to the taper surface, and permit each member to absorb 25 per cent of the basic allowance between the reamer face and the face of the arbor collar, so that should the reamer hole be made to the maximum diameter and the arbor surface to the minimum, there would still be left 50 per cent of the allowance to provide for wear. The limits on the diameter of the hole in the reamer at the large end and the diameter of the arbor at the gaging point, and the tolerance on these diameters, are given in Table 2.

On account of the fact that it is impossible to machine the driving lugs of the arbor in absolute alignment with the center of the reamer hole, a tolerance *X* is established to meet this condition. The formula for this tolerance is:

$$X = \frac{0.40\ (C - A)}{2}$$

in which

X = amount each member may be off center in either direction;

C = minimum (basic) width of slots in reamer; and

A = maximum (basic) width of lugs on arbor.

The difference between a minimum width slot and a maximum width lug is 1/64 inch in all cases, and so the solution resolves itself into

$$X = \frac{0.40 \times 0.015625}{2} = 0.003125 \text{ or } 0.003 \text{ inch}$$

for every size of reamer.

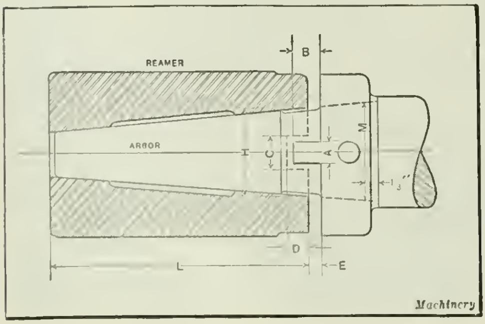


Fig. 1. Illustration showing on an Exaggerated Scale the Fit of a Shell Reamer on its Arbor

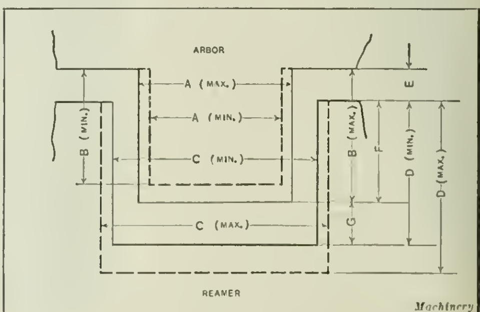

Fig. 2. Diagram showing Limits on Driving Lugs and Slots of Reamers and Arbors

It will be seen that in allowing the slots in the reamer and the lugs on the arbor to be off center an amount equal to 40 per cent of the smallest clearance, there still remains 20 per cent of that clearance even though both members should be out of true the maximum amount in opposite directions. Table 3 gives the maximum and minimum limits both for arbor lugs and reamer slots, as well as the driving length *F*, Fig. 2, and the clearances *E* and *G*.

The Master Gages

Before starting the manufacture of reamers and arbors, it was necessary to establish a sequence of operations and a system of gaging, the first gages required being three master gages. That known as the "master reamer" is shown in Fig. 3. The hole and the slots are made to very small tolerances, and correspond as nearly as possible to the dimensions of a reamer having a minimum diameter hole and size of slots, and any arbor which fits this gage will fit any reamer passing the inspection gages. The driving lugs and the taper surface of the master arbor illustrated at *V*, Fig. 7, are made to very small tolerances, and correspond to the dimensions of a maximum size arbor. Consequently a reamer which fits this gage will also fit any arbor passing the inspection gages.

Testing the Taper of Master Taper Plug Gages

The master taper plug gage shown at *W* is used in the manufacture of the other gages, the correct taper being determined within very close limits by setting up a pair of parallels with two different sizes of B. & S. ground disks spaced the proper distance apart by means of standard gage-blocks, as shown in Fig. 4. The middle line *H*, Fig. 7, of the three etched lines on the gage is located at a point where the tapered part is equal in diameter to the basic gage dimension *H* in Table 1, and the other two lines are located at points where the tapered part is equal in diameter to certain of the inspection gages ground to this master. All the gages considered in this article have a flat surface to provide a space for identification marks, such as the tool number, basic diameter, number of hole, trademark, and the block letter S previously mentioned. Master gages are also stamped with a letter M to distinguish them from inspection gages, which are stamped with the letter I.

TABLE 1. REAMER AND ARBOR DIMENSIONS ADOPTED BY THE DRILL AND REAMER ASSOCIATION*

Arbor No.	Diam. of Reamer Hole, Large End, Inches	Arbor Lugs		Driving Slots		Reamer Length, Inches

Machinery

*See Fig. 1 for the notation in this table.

Manufacturing the Reamers and Arbors

As this article deals with the fit of shell reamers and their arbors, only such points in their manufacture as affect the fit will be considered here. The first operation on a reamer consists of reaming the hole to fit the plug gage shown at *X* in Fig. 7. Line *H* of this gage should be about 1/2 inch from the large end of the reamer to allow about 0.005 inch of stock in the hole for grinding after hardening. After that operation the gage must go into the reamer hole to line *H* at which point the diameter is the basic dimension given in Table 1. An axial tolerance *K*, equal to that specified in Table 2 for the proper size of arbor, is permitted.

Previous to hardening the reamer, the driving slots are milled to the limit plug gage shown at *X* in Fig. 5. On this, the "Go" and "Not Go" gaging surfaces are made to the minimum and maximum dimension *C* given in Table 3. As the depth of the slots has a tolerance of 1/64 inch, a scale measurement is considered sufficient in determining this dimension. After milling the slots, their alignment with the center of the hole is tested by means of the gage shown at *Z*, Fig. 7. A sliding sleeve on this gage carries a lug of a width *R* which is equal to the width of the minimum slot on a mating reamer, as given in Table 3, minus 0.006 inch to allow the slots to be off center 0.003 inch in either direction. After hardening the reamer and grinding the hole, this gage is again used to ascertain whether the slot width has changed in hardening; if this is the case, the interference must be ground away.

By again referring to Fig. 1, it will be seen that an arbor consists of two parts, a collar being driven on the arbor proper and pinned to it. The arbor proper is first turned to suit the gage shown at *X* in Fig. 6, on which diameter *M* corresponds to diameter *M* in Fig. 1; this dimension is 0.010 inch larger than the finished diameter of the tapered part carried to a point 1/8 inch from the shoulder provided on the arbor for seating the collar. The short pin projecting from the face of this gage is intended to come flush with the shoulder on the arbor or not reach it, while the large plug must reach the shoulder. The long pin is 0.400 inch longer than the short one and allows from 0.010 to 0.014 inch of stock on the diameter for subsequent grinding. The arbor

is finally recessed, as illustrated in Fig. 1, in order to facilitate the grinding of the taper surfaces after the collar is pressed on.

The arbor collar is first reamed to suit the requirements of the plug gage shown at Y, Fig. 7, on which the larger diameter of the etched band is the same as diameter *M* on the gage at *X* in Fig. 6. Thus should a maximum size collar and a minimum size arbor be assembled, there would be an axial allowance of 1/8 inch for a driving fit. If this allowance is exceeded, the collar must be reamed again until it rests 1/8 inch from the shoulder of the arbor. By this method there is always sure to be sufficient stock for a driving fit.

The lugs on the collar are next milled to the correct widths, as determined by the gage shown at *Y* in Fig. 5, the gaging surfaces of which are made to the maximum and minimum dimensions *A* in Table 3. As a tolerance of 1/64 inch is allowed on the length of the lugs, scale measurement is considered sufficient for determining this dimension. The

Machinery

*See Fig. 2 for the notation in this table.

alignment of the lugs with the center of the hole is tested by means of the gage *Z*, Fig. 5, on which dimension *T* equals one-half the maximum dimension *A*, Table 3, plus 0.003 inch to allow a maximum lug to be off center 0.003 inch. It will be obvious that a minimum width lug can be off center more than a maximum width lug.

After milling these driving lugs, the collar is fitted, pressed on the arbor and pinned in place. It is then turned down flush with the arbor shank, and the taper surface of the arbor ground to the flush-pin gage shown at *Y* in Fig. 6. The large end *V* of the hole in this gage is ground to a diameter which, on a finish-ground maximum size arbor, causes the face of the gage to rest 1/8 inch from the lugs on the arbor collar. In this position if one end of the sliding pin is placed against the face of the collar, the other end will be flush with the lower step on the rear end of the gage. On a minimum size arbor, the gage will rest closer to the lug and the rear end of the sliding pin will be flush with the high step.

The last gage used in the inspection of an assembled arbor and collar is that shown at *Z*, Fig. 6. This is used to make a final test of the alignment of the driving lugs with the center of the arbor. Dimension *W* is equal to one-half of the maximum dimension *A* as given in Table 3, plus 0.003 inch, and if an arbor passes this gage, it is pronounced satisfactory. It will be apparent that this gage is used for testing both sides of the lugs. In the tables arbors Nos. 1 and 2 are not considered, as they are special sizes and seldom used.

ACTIVITY IN THE RAILWAY FIELD

While the railroads have not as yet placed large orders for machine tools, they have started a buying campaign which doubtless will be extended to the tool equipment field. The net operating income of the railroads has steadily increased, and their financial position today is better than it has been for many years past. Up to May first 52,000 freight cars had been ordered—a larger number than has been ordered in any year since 1918. It is evident that the railroad managers are looking forward to heavy freight traffic. The increased activity in railroad buying has favorably affected the sales of electric furnace equipment as reported by one of the electric furnace companies. These furnaces are used for manganese steel castings for railroad purposes.

DULLNESS IN FRENCH MACHINE TOOL MARKET DUE TO UNCERTAINTY

A well-known representative in France of an American manufacturer of metal-working machinery states that the stagnation of the French market in machinery of this type is due to the inability of the consumer to foretell the financial situation with any certainty, and the manufacturer who would bring his plant up-to-date with modern equipment is unable to do so, because he cannot determine whether or not there will be any returns on the investment. The manufacturer who finds that he can buy a machine tool of either French or German make very much cheaper than an American machine, naturally will turn either to the home industry or to the German market—sometimes without a thought as to whether the machine that he buys will actually serve his purpose as well as the more expensive American product.

As a matter of fact, he does not know definitely what the relative values of the machines are, because he has nothing upon which to base his judgment but the enthusiasm of the parties most interested—the French distributor of the American machine on the one hand, and the French or German manufacturer on the other. Furthermore, he often fears that it would be difficult to obtain repair parts in case the American machine is not one that is well known and generally used in France. He had the same idea about Ford cars and Kodak cameras, but he has changed his mind because these big-scale American producers have realized that they had a big market, and they were able to cultivate it until they ultimately found that they had a better field to till than they had expected.

Is there any way out for the American machine tool manufacturer? The larger ones possibly could manufacture, or at least assemble, in France. This would be one way, and perhaps the only way, in which to overcome present difficulties. In that case association with the right kind of French industrial enterprises might be desirable. The idea may be impracticable, but it would be worth while investigating.

* * *

The improvement in the iron and steel field is encouraging. Structural steel particularly is in great demand. Orders for fabricated structural steel placed during April were almost equal to the capacity of the fabricating firms.

Tool Supply and Stock-carrying Methods

A Description of a Tool Supply System in a Contract Plant and a Discussion of the Inspection and Repair of Equipment and the Carrying of Adequate Stock

By GEORGE H. SHEPARD
Professor of Industrial Engineering and Management, Purdue University

TOOL issue rooms or tool cribs, as they are commonly called, are found in almost every machine shop. Here tools are taken care of and issued to the workmen without delay, and records are kept of the men to whom the tools are lent. In large shops, it is usual for each department to have a tool issue room, and in such cases it is a good plan to have a central tool store-room in which reserve stocks of standard tools are kept and supplied to the issue rooms as required. The tool supply system should be so organized as to render the best possible service to the shop, and in order to attain this end, the tool store-room and all issue rooms should be under the authority of one foreman responsible to the general foreman. The tool foreman should turn over all routine work to subordinates so that his time may be devoted to supervising the force and attending to the more important matters that arise. Every other man in charge of a section of the tool supply system should be held strictly accountable for the condition of tools or records under his care and for the quality of service rendered by his section.

The equipment of the tool store and issue rooms consists primarily of facilities for stowing tools in the most accessible manner. Open shelves should be used whenever possible, and bins or pockets may be employed when it is necessary to prevent the stock from rolling on the floor. Drawers should be used only as a last resort, because they hamper inspection and encourage careless stowing. Revolving racks and other special equipment are sometimes necessary to facilitate stowing or handling. The heading illustration shows a tool issue room in which the tools are stored in an ideal manner. The stock that is on hand of each particular tool should be large enough to meet all reasonable demands of the shop, but care should be taken not to overstock.

In the following some of the duties of the members of a tool supply system are outlined.

Duties of the Tool Store and Issue Room Forces

Tool Foreman—The tool foreman is in complete charge of the tool store-room and the tool issue rooms, and is directly responsible to the general foreman. He should personally attend to the following duties, or see that they are definitely assigned to competent assistants: Assigning all new tools to the proper inventory class, depending upon whether they are standard, odd sizes, or special; examining all damaged tools and arranging for their prompt disposal; rendering a decision on any question as to the serviceability of such tools as short taps and badly worn dies; conferring with the technical advisor concerning special tools for new machines and procuring those necessary; issuing requests for new tools after reviewing the reports of the tool storekeeper and making a careful study of the tool inventory; and arranging for a periodic checking of the tool inventory, so the total inventory will be checked at least once a year.

Tool Store-keeper—The tool store-keeper should be next to the tool foreman in charge of the tool store-room, and should be responsible for keeping the records, including cards and damage reports. Three special inventories should be kept, one each for standard, odd-sized, and special tools. The inventory of all standard tools in the tool store-room, the tool issue rooms, and the forging shop for redressing, may be kept on a form such as illustrated in Fig. 1. The back of this card is identical with the front so as to permit the use of both sides. The balances on these cards should control the ordering of new tools. All cases of shortage and demands for new tools should be reported to the tool foreman. Whenever tools are requested, the date, requisition

Fig. 2. Form used for keeping an Inventory of Odd-sized and Special Tools

number, and number of tools desired should be entered on the inventory cards under the heading "Ordered," and this entry should be checked off when the lot is received.

The inventory of odd-sized tools may be kept on the form shown in Fig. 2, the back of which is the same as the lower part of the front. Odd-sized tools should be handled in the same manner as standard tools, except that no reserve stock should be carried. They should be replaced or repaired as they become damaged, proper entries being made on the card. The inventory of special tools may also be kept on the form shown in Fig. 2. This class of tools should be handled in the same manner as standard tools, except that no reserve stock should be carried and they should not be replaced when damaged. When a special tool is discarded, the fact should be noted on the inventory card, and the latter removed from the file. The tool store-keeper should receive all new tools, and record them in the inventory file according to the classification assigned them by the tool foreman, and he should take care of reports and records of tools lost or damaged.

Supervisors of Issue Rooms—Each issue room or section of the tool store-room should be under the charge of a supervisor responsible to the tool foreman for the condition of tools under his care. The supervisor should frequently inspect all tools ready for immediate use and dispose at once of damaged or partly worn tools that may get into the racks. Doubtful questions as to serviceability should be referred to the tool foreman, as previously mentioned. He should also see that tools and receipt checks are in their proper places. As far as possible, tools should be stored according to their class; for example, lathe and planer tools should be placed in one section, taps and dies in another, and milling cutters and slitting saws in a third. Odd-sized tools should be kept with standard tools of the same kind, but special tools should be kept in an entirely different section. Standard tools of any one kind should be arranged according to their principal dimensions.

Caring for Precision Instruments

All precision instruments, such as micrometers, gages, straightedges, and vernier calipers should be returned to the tool issue rooms at the close of each working shift. These instruments should be kept separate from other tools, and before being placed in racks for re-issuing, they should be compared with working standards. The latter should never be issued or handled by anyone except the supervisor of the tool issue room. It is also well to remove any scratches or other blemishes from micrometers and gages before storing them for re-issue.

If the results are to be strictly reliable, there must be a routine system for adequate checking of the working standards. In a plant of considerable size there would probably be a precision laboratory, in which the working standards would be periodically checked against plant standards. At long intervals the plant standards themselves should be checked by the Bureau of Standards in Washington.

Inspection and Repair of Equipment

An anticipative inspection and preventive repair system is applicable to contract as well as manufacturing plants. Under this system, the equipment is listed and a definite interval is set for the inspection of each piece. At the appointed time, the equipment is examined by an inspector of the maintenance department, all work necessary to keep the equipment in working order is noted, and the work is done as soon as possible. The only peculiarity of this system as applied to the contract plant is that the inspection intervals are more difficult to set than when a plant is operated on a manufacturing basis, because of the irregular use of many of the machines. However, it has been found practicable to carry out this system so as to increase materially the reliability of the equipment and the chance of its being available when wanted. In a contract plant this factor is especially important, because there is often a sudden demand for the use of some equipment, and the need is likely to be an urgent one.

Before the installation of a system of this kind, supervisors generally are accustomed to calling for repairs to their equipment as they see necessary. They should continue to do this under the new system and should not place an overdependence on the system, or wait for the maintenance department to learn of the need of repairs in its routine inspection. The arrival of the time for this inspection does not justify the inoperation of equipment urgently needed; if necessary, the inspection should be delayed until a more convenient time. When an inspection of a piece of equipment is to be made, the inspector should interview the workmen and supervisors who operate the equipment and obtain a statement of their experience with it since the last inspection. By means of this information and such an examination of the equipment as may be possible during its regular operation, it may often be decided that a disassembly of the equipment is unnecessary.

Clamps, bolts, steadyrests, and other auxiliary equipment of machines should also be inspected regularly. It will often be found that the stock of such equipment is seriously depleted, in which case a replacement must be made. Such of this equipment as serves several machines is best kept in the tool-room when not in use, but articles that serve one machine only are often most conveniently located near that machine, provided arrangements are made to insure that the parts will not be carried away by unauthorized persons. In Fig. 3 is shown a method of locking wrenches to a machine to prevent losing them. Fig. 4 shows a lathe having a number of pieces of auxiliary equipment, including a tool box on the floor, a stand for collets and instruments, a portable light, and a crane for assisting in mounting or dismounting the chuck.

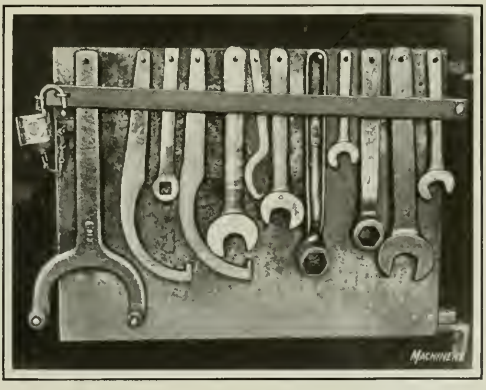

Fig. 3. Method of locking Wrenches to a Machine to prevent them from being lost or removed by Unauthorized Workmen

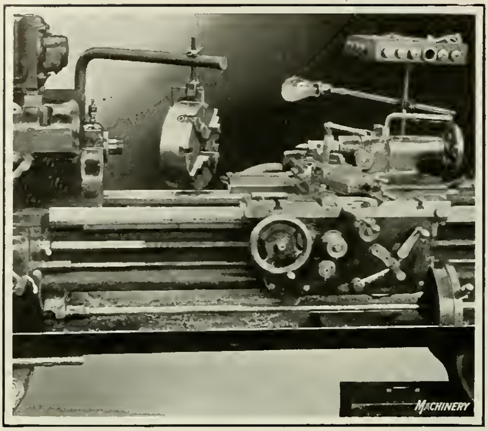

Fig. 4. Engine Lathe provided with such Auxiliary Equipment as a Chuck Crane, a Collet and Instrument Stand, and a Tool Box

Stock of Raw Materials and Completed Parts

The carrying of a reasonable stock of raw materials and completed parts is essential to the prompt filling of emergency and rush orders which are so common in contract or jobbing plants. Carrying a stock of completed parts also enables a plant to produce in quantities great enough for efficient operation, instead of wastefully making driblet orders of parts to customers' orders. However, with the continual change of work in these plants there is always a risk that any stock except that most essential will lie indefinitely in the store-room and perhaps never be used. The files of instruction cards of former work shown in the article "Planning in Large Contract Plants" in March MACHINERY, furnish the best data from which to decide what raw materials and completed parts should be carried in stock and between what limits. In the absence of such data, it is necessary to rely on the estimates of persons whose work brings them in touch with the subject. Experience has shown the great superiority of actual records. The estimates of such persons are of great value in correcting the figures of the past for the probable changes of the future, a matter which the jobbing plant least of all can afford to overlook.

In order to get the full benefit of the system of carrying stock, the planners must be kept fully informed of the stock on hand, as otherwise instead of drawing parts from stock, they will order them made in small quantities to suit a customer's order. To give planners adequate information along these lines, it is necessary to furnish them with an up-to-date stock catalogue. The difficulty of providing such data indicates that the decision as to drawing parts from stock or making them to order, should be made by the central planning office, because a small force of specially expert material men can be maintained there for this particular purpose.

One of the problems of keeping stores is to save materials left over. In a foundry having many emergency orders, where an excess allowance is molded and poured equal to a reasonable estimate of scrap loss, some castings are often left over. In a smith shop, also, ends of billets are left over, and in boiler shops, there is an excess of tube ends and plate clippings. Any shop will leave over broken packages of small articles usually bought outside. A convenient means of saving such materials is to establish a store-room in the shop, especially for left-over parts. Unless this is done, these parts are likely to lie about the shop indefinitely, contributing to the disorder of the shop and frequently resulting in a dead loss. The shops in a contract plant are often more or less inaccessible to the general store-room, and when much outside repair work is done it may be necessary to have small semi-detached shops on barges or railway cars. The degree of accessibility to the general storeroom determines the amount of supplies which should be carried in their stores.

Salvaging Scrap and Discarded Parts

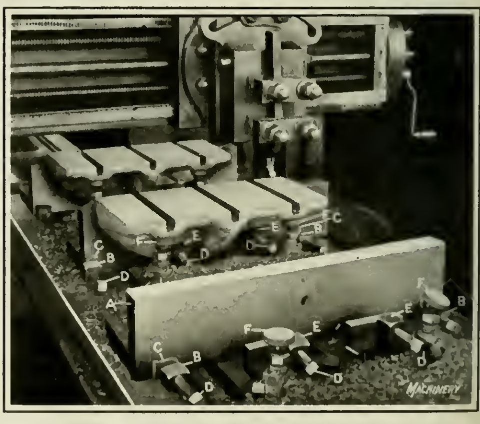
A repair shop, on account of the nature of its business, rapidly accumulates considerable scrap. The method of handling this material may make it a source either of expense or of considerable revenue. If the latter is to be the case, such materials must be handled by a competent salvage department. The first requisite for the efficient salvaging of this material is that it should be well sorted. This requires considerable room, but buildings of the cheapest construction, or even open bins, suffice. After it has been classified and sorted, the disposal of the material to the best advantage depends upon the skill of the salvage department, either in using it in the plant or selling it.

* * *

FIXTURE FOR PLANING ANGLE-PLATES

The accompanying illustration shows a Woodward & Powell planer set up for planing the top surface of an angle-plate for a Pratt & Whitney 6-inch vertical shaper. Before the operation is performed, the surface at the back of the work is finished, and this is used as a locating point for clamping the casting against an angle-plate fixture. A string of these castings is set up for planing. The arrangement of the clamping bolts, jacks, etc., may be clearly seen in the foreground, where one of the fixtures is shown with the casting removed. Provision must be made in this operation for supporting the end thrust of the tool, and this is accomplished by having stops *B* set in the table T-slots, which carry bolts engaging the front face of the fixture *A*.

In order to avoid damaging the finished surfaces of the fixtures, a sheet-metal shim *C* is placed between each clamping bolt and the fixture. It will be seen that there is a thin wall on each casting, the back face of which has already been planed, and this face is clamped against the fixture by two bolts *D* which are carried by stops *E*. The work is supported against the vertical pressure of the tool by means of two jacks *F*, the upper members of which are furnished with a ball and socket connection so that they will automatically adjust themselves for slight irregularities in the castings, and afford a uniform support. On this job the depth of cut is 1/8 inch, with a feed of 1/4 inch per table stroke and a cutting speed of 20 feet per minute, the material being cast-iron.



Planer equipped for planing the Tops of Angle-plates for Vertical Shaper

Building Special Machines for Can-Seaming

By ARTHUR MUMPER

MACHINE work of an interesting nature and calling for a high degree of accuracy is frequently met with in shops devoted to the construction of special machinery. The building of special machines, such as the can-seaming machine shown in Fig. 1, always has an interest for the machinist, and the shop doing this class of work usually experiences less difficulty from labor turnover than that engaged in general contract or repair work. In the plant of the Ackermann Mfg. Co., Wheeling, W. Va., where the Wheeling No. 100-A double-seamer shown in Fig. 1 is built, the work is done on a production basis, yet the management takes care not to advocate stereotyped high-production methods to the extent of lessening the men's interest in their work and killing any incentive for them to develop original methods of increasing production.

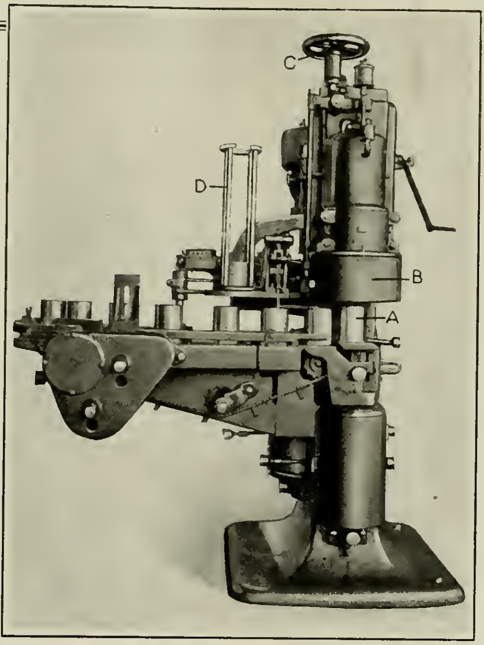


Fig. 1. Automatic Can-seaming Machine

A general line of machine tools is usually required in the manufacture of special machines like the double-seamer, or "can-closing machine," as it is also called. The machine work required in building the can-closing machine, like that required in building many other special automatic machines, includes gear-cutting and cam-cutting operations such as are seldom met with in repair shop work. The making of improvements on special machines taxes the ingenuity of the machinist in devising adequate means of machining new parts and thus increases interest in the work.

The can-closing machine represents a highly developed type of a strictly single-purpose machine. This machine is used to close the ends of cylindrical tin containers or cans after they have been filled at the packing plant. It is a patented machine, and it is claimed that it has a smaller number of working parts than any similar machine that is employed for the same purpose.

Operation of Can-closing Machine

The empty cans are placed in a trackway, and roll by gravity to an automatic filling machine. After being filled, they pass on to an endless belt which conveys them to the closing machine or double-seamer. The double-seamer handles the filled cans at the rate of sixty a minute without spilling the contents. It also straightens the cans, which are not perfectly round, before seaming the tops to the bottoms. The cans are not handled by the operator from the time they are first placed in the trackway until after they are packed and the ends seamed tight. After this seaming operation the cans will stand a pressure of from 40 to 45 pounds per square inch without leaking.

The curled edge of the can-end is rolled in under the flanged end of the can body which is thus made air-tight. This is done in two operations; the principle is practically the same as that involved in the construction of other can-closing machines, the can body being carried into the machine where it is held firmly in a stationary position while the seaming-head is forced in against the edge of the lid or can cover and revolved at a high rate of speed. The seaming head carries two seam-rollers of tool steel which are hardened and ground and mounted on roller bearings.

In the finishing machine, Fig. 1, a can is shown at *A* under the chuck. This can is being held up against the seaming chuck by the plunger-plate which is corrugated to prevent the can from turning. Directly above the third can from the right is the marking device. This attachment can be set with type to mark the ends with any impression desired. Just above the fourth can from the right is the magazine, which holds a stack of can ends. These ends are separated by the can as it passes through the can-guides and engages with an index-lever. The can-end passes along with, but just above, the can body until after the end comes from the marker, when it drops down in its place on the can.

Construction of Machine

The cans are carried from the filling machine on an endless belt, and are placed on a revolving table at the left-hand end of the seaming machine. This table moves them along until the dogs on the chain shown just under the table carry them under the plunger-plate, ready for the seaming operation. The seaming head is composed of an inner sleeve, which is a running fit in an outer sleeve. The outer sleeve runs on two tapered roller bearings. The inner sleeve is bored out to clear the chuck shaft which passes through the entire seaming head, and it has a bearing on the chuck shaft at one end. The chuck shaft is bored to clear the cam-operated knock-out, which forces the can from the chuck after the completion of the seaming operation.

Fig. 2. Cams used in Machine shown in Fig. 1

The cam that operates the knock-out is shown at *A* Fig. 2. The plunger-plate is also forced up by a grooved cam which is shown at *B*. At *C* is shown the topper cam, which is similar in design to the plunger cam. The seaming is done by a cast-iron cam *D*, which is provided with a hardened and ground tool-steel center. This cam is contained in the seaming head *B*, Fig. 1. The handwheel shown at *C* provides means of making vertical adjustments. The mold-carrier cam, which actuates the mechanism by means of which the can body is placed on the plunger-plate, is shown at *E*, Fig. 2. It will be noted that this cam is provided with gear teeth on its periphery. The making of this cam, as well as the others in Fig. 2, calls for fine machine work.

A different size magazine is required for each size of can handled by the machine. The machine is belt-driven, and power is transmitted through a large steel worm-gear. By the extensive use of jigs and fixtures in the manufacture of the various parts entering into the construction of this machine, the element of inaccuracy is reduced to a minimum. Special care is taken in the design and construction of the jigs and fixtures to provide for means of facilitating the handling and setting up of the work for the different machining operations. All parts that must be counted on to retain their shape are seasoned after the roughing cuts are taken. Particular care is taken in seasoning the casting of the cover feed-plate shown at *F*, as this part is required to be very accurate.

* * *

A lighting code for factories, mills, and other working places, based upon earlier codes issued by the Illuminating Engineering Society, and recently revised by a sectional committee under the sponsorship of this society, has been officially approved as standard by the American Engineering Standards Committee. The code is very brief, consisting of a few rules covering methods of avoiding glare, and the minimum requirements, from the point of view of safety, for exit and emergency lighting. Supplementary to the code are numerous suggestions relative to illumination for different classes of work and an outline of the advantages of good lighting.

GRINDING TRIMMING DIES USED IN SHOVEL MANUFACTURE

By C. F. GEORGE

The dies used in trimming round-point shovel blanks are usually made in two parts. The cutting members or blades are made from 3- by 3/4-inch shear steel, and they are fastened to cast-iron bolsters in the manner indicated in the enlarged sectional view in the lower right-hand corner of Fig. 1. This construction permits the bolster to be fitted to the bolster-plate *A* or to the upper die-plate *B* to suit the size of shovel to be trimmed. The shovels are usually made with a uniform variation of 1/2 inch between sizes on the width and length, unless otherwise specified, and the radius of curvature of the die blades for all shovel sizes is the same. By drilling a series of holes in the bolster-plate and upper die-plate, spaced to agree with the size of shovel being trimmed, adjustment for width will enable one set of die blades to be used on all standard sizes of shovels. The blades, which are forged to shape, are fastened by dowels and bolts to the bolster, as previously stated, and when assembled to their respective plates, have the general arrangement indicated in the sectional view *D*.

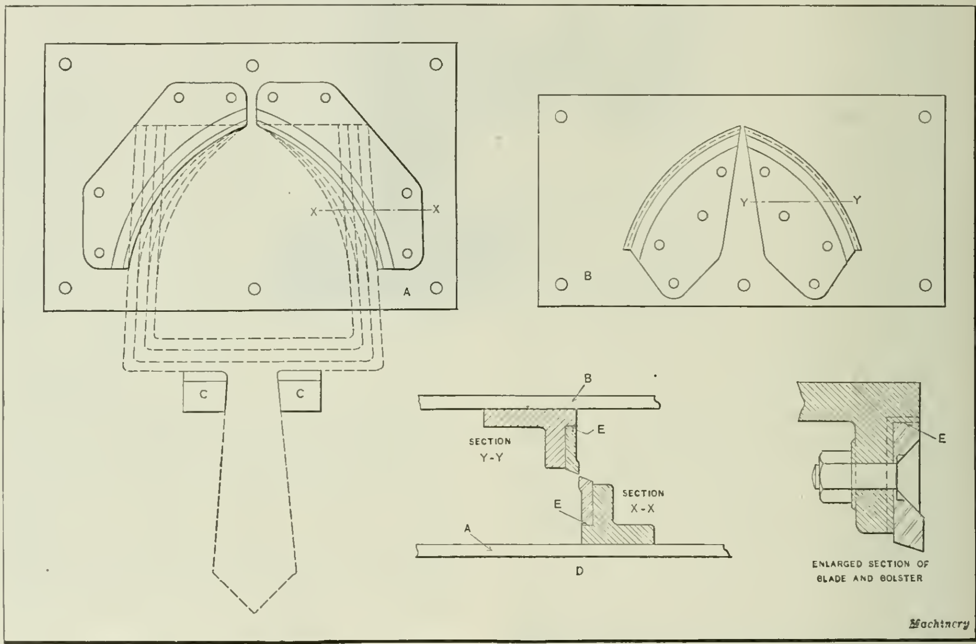

Fig. 1. Arrangement of Blades of Trimming Dies used in the Manufacture of Shovels

In assembling the bolsters to plates *A* and *B*, they are first ground to form a seat and then holes are drilled for the bolts by means of which they are attached to the plates. Surface *E* is also ground to form a seat for the blade, and bosses are cast on the plates for the bolt holes. These bosses are carefully filed to gage height, and provide an even support for the blades. This is an economical way of obtaining the desired fit, as it obviates finishing the entire bearing surface. The bottom dies are shown in the left-hand part of Fig. 1; in this view the relative contour of shovels of different sizes and the position which the blanks occupy during the trimming operation are indicated by dotted lines. It will be seen that the blanks are brought up against two stops *C*, the transverse adjustment for the bolster plate being obtained by means of the T-slots in the bed of the press. The upper die-plate *B* is attached to the ram, and it is in

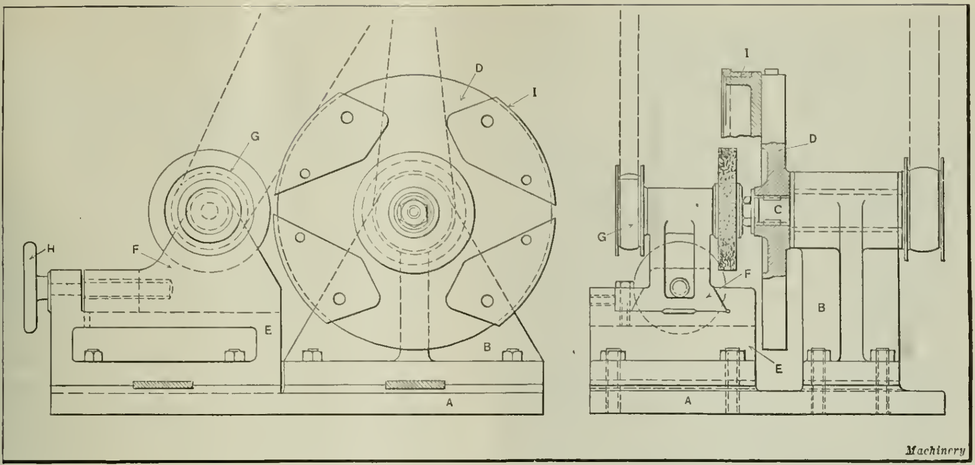

Fig. 2. Fixture for grinding Cutting Edges of Upper Die Blades

relation to the upper dies that the lower die-plate *A* is adjusted. After the upper and lower dies have been located on their respective plates by the holes for the particular size shovel to be trimmed, they are bolted down and tested on a bench, before being put into use. All the shear is put on the upper set of die blades which perform the trimming, the lower dies not being provided with shear.

Before being used, the bolsters and assembled blades are ground with the special grinding equipment shown in Figs. 2 and 3. The fixture for grinding the cutting edges of the upper die blades is illustrated in Fig. 2. This consists of a cast-iron base *A* to which is bolted the spindle bearing stand *B*. The upper part of this stand is the bearing box for the spindle *C* which carries the flanged driving pulley and the faceplate *D*. On the cast-iron base is also mounted the grinding wheel head, which consists of a cast-iron support *E*, in which the wheel-slide *F* is carried.

The slide casting contains the bearings for the short shaft that supports the pulley *G* at one end and the grinding wheel at the other. The blades *I* are bolted to the faceplate *D* by means of the bolsters to which they are fitted, slightly elongated bolt holes being used to allow for angular adjustment. After the bolsters and blades have been properly adjusted, the grinding wheel is traversed up to the face of the blades by operating the handwheel *H*. The uniform curvature of the cutting edges of the blades can thus be readily established and checked by the use of calipers. The grinding wheel is operated at a speed of 3000 revolutions per minute and the faceplate at 60 revolutions per minute in the opposite direction, both the wheel and the faceplate being driven by belts from the lineshaft.

The grinding fixture used in grinding the lower die blades is of equally simple construction, as shown in Fig. 3. It consists of a cast-iron base *A* to which the driving shaft bearing *B* is bolted. The driving shaft carries a flanged pulley by means of which the faceplate *C* is driven. The grinding wheel shaft is supported in roller bearings, mounted at each side of the driving pulley *D*, these bearings being housed in the top slide *E*. Slide *E* may be adjusted in the bottom slide *F* by means of a handwheel and traverse screw, a similar construction also being provided for the crosswise movement of slide *F*. Adjustable guide strips *G* are provided for the top slide, and a tapered gib *H* compensates for wear on the lower slide. The radial adjustment of the grinding wheel to obtain the correct curvature of the cutting edges of the blades is accomplished by operating handwheel *J*.

As in the method of attaching the top blades, elongated holes in the faceplate allow for making angular adjustment when

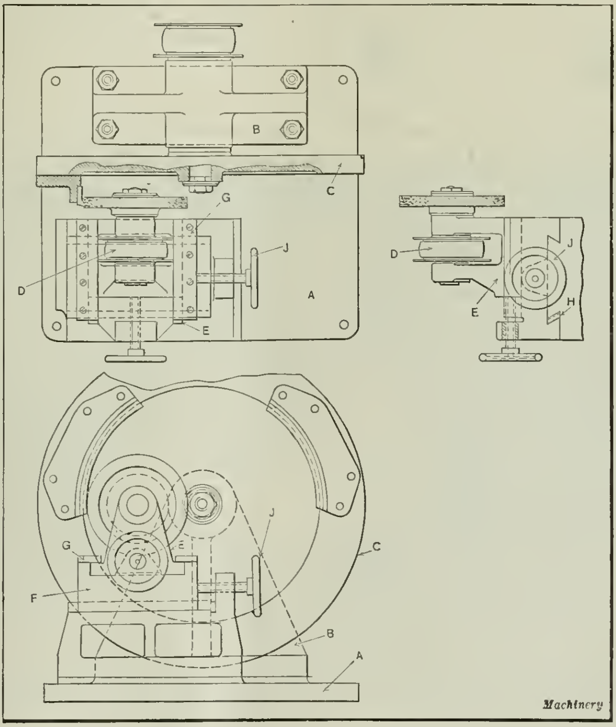

Fig. 3. Design of Fixture in which the Lower Die Blades are ground

attaching the bolsters and blades to the faceplate. This slight elongation is not shown in either Figs. 2 or 3. The inside diameter of the cutting edges of the bottom blades, when assembled to the faceplate, should be 0.010 inch greater than the outside diameter of the upper blades. This provides the necessary clearance between the dies when in use. The grinding wheel and the faceplate are driven from the line-shaft, and the same rotative speeds are used as are employed when grinding the upper blades. One set of trimming dies has produced 12,000 blanks before being reground. For average conditions it requires about one-half hour to set up and grind a pair of blades.

PATTERNS FOR CHECKED FLOOR-PLATE CASTINGS

By M. E. DUGGAN

Cast-iron stair treads and floor-plates are easy to keep clean and are very strong when properly supported. They are therefore used to a considerable extent in shops and factories. Pattern material for producing the checked surfaces that are required to prevent workmen from slipping on them can be obtained from companies that deal in patternmakers' supplies. Material of this kind usually has diamond-shaped checks cut in one side, although other designs are sometimes employed.

This stock is ordinarily obtainable in thicknesses ranging from ½ to ¾ inch. In some cases patternmakers are required to cut and shape the diamond checks in patterns for stair treads or floor-plates. This is a slow and tedious job, however, and is seldom attempted when it is possible to obtain stock already provided with checks of the required size and shape. The following method of constructing a pattern for molding four checked floor-plates, *A*, *B*, *C*, and *D*, of the dimensions shown in Fig. 1 was recently observed by the writer in a jobbing shop.

Skeleton frames conforming to the outlines of plates *A* and *B*, and one frame for plates *C* and *D*, were made from 1- by 1¼-inch pine stock. One of these frames is shown at *E*, Fig. 2. In making the mold, the frame and drag flask are first placed in position on the bottom board. The space within the frame is filled in with boards 1 inch thick, or the thickness of the plate. These filler boards are furnished with the pattern and can be made from scrap lumber. It is not absolutely necessary that they be fitted tightly; all that is required is that they be flat and of uniform thickness. Sand is next filled in up to the top of the flask, and the mold made in the usual manner. The drag is then rolled over, the cope flask placed on it, and the cope mold completed, after which the cope flask is lifted off.

By placing the loose pieces within the frame, the latter is practically converted into a one-piece pattern so that no digging out or disturbing of the mold is necessary. A better casting is produced from a mold made in this way than would be the case if no filler boards were used and the "digging-out" method employed. After the cope has been lifted out the filler pieces are removed, leaving the frame in the mold. The diamond checks are then made in the bottom face of the mold. First a block of wood *F*, Fig. 2, is cut and finished to a convenient size (in this case 6 by 12 by 1⅛ inches). Diamond checks are then cut in one face of this block. The block is next fastened to the gage-board *G*. The ends of this board are made long enough to overlap the drag flask in order to allow the block to be shifted back and forth over the frame. In the illustration the gage-board *G*, with the block *F* attached to it, is shown in position for making the first impression of the diamond checks in the face of the mold. A few taps with a hammer on the gage-board is sufficient to make the required impression. The block is next moved to the opposite side within the frame and another impression made. This process is continued until the whole face of the mold within the frame has been given the impression of the diamond checks.

Only one frame is required for plates *C* and *D*, as it is only necessary to reverse the position of the frame on the bottom board when making the mold for a plate of the opposite hand. Before moving the diamond-checked block ahead, a mark is made on the frame and the opposite edge of the gage-board then brought flush with this mark. If the work is properly carried out, the face of the casting will appear as if made from a full pattern. This method, of course, adds to the work of molding, but results in a saving in material and time, as it does not require the making of a full pattern. Another advantage is that there is no large plate pattern to be handled or stored away in the pattern loft where it is likely to become warped and twisted. It may be mentioned that the thickness of the frame is the same as the thickness of the cast plate minus the depth of the diamond checks. In this case the cast plate is 1⅛ inches thick, the diamond checks ⅛ inch deep, and the frame 1 inch thick.

THE COST OF BUILDING

The Bureau of Labor Statistics, Washington, D. C., has published a chart and a tabulated statement showing the increases in wages in the building trades and in the price of building materials since 1913. This statement shows that at the present time the average wages in all of the building trades combined are almost exactly double what they were in 1913, and the average of all building materials shows an increase of about 55 per cent over the 1913 figures. Brick has been reduced the least from the peak prices, prices of common brick being still double the 1913 prices. The average price of lumber is 65 per cent above the 1913 figure.

Checking the Accuracy of Lead-Screws

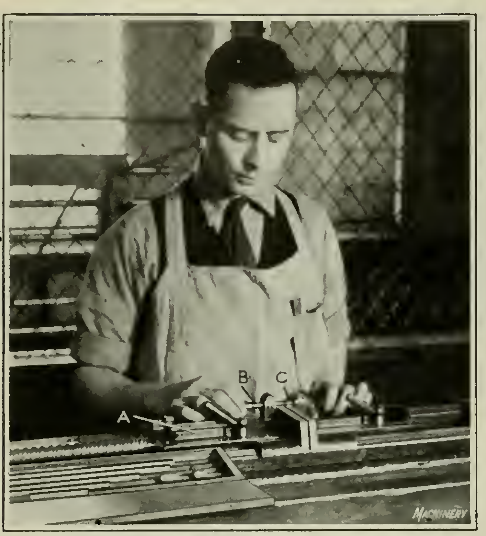

Fig. 1. Adjustment of Micrometer Spindle and Anvil Preparatory to checking Lead-screw for Lead Errors

When lead-screws are checked for accuracy at the plant of the Pratt & Whitney Co., Hartford, Conn., the test is based on the action of a nut relative to the screw, or the distance that the nut moves for a given rotation of the screw, as compared with the movement that would be obtained if the screw were perfect in lead. This simple method of using a nut and basing tests upon its movements is employed instead of attempting to determine the accuracy by a series of local tests along the screw itself, because, after all, it is the movement imparted to the nut that is important when the screw is applied to a lathe or other machine.

The testing fixture used for lathe lead-screws is very simple, as Figs. 1 and 2 indicate. There is a rigid bed long enough for any of the screws manufactured. This bed has accurate ways, and a block *A* which is free to slide along the ways and which carries a nut conforming to the diameter and pitch of the lead-screw to be tested. The nut can be replaced readily by others of different size and pitch when lead-screws of different sizes are to be tested. The sliding block carrying the nut also carries a micrometer head *B* which is opposite an anvil *C* held in another block mounted on the ways. The latter block may be shifted along the bed to whatever section of the lead-screw is being tested, but it is clamped in position for taking measurements. At one end of the lead-screw there is an index-plate *D* (Fig. 2) which provides for turning the screw exactly one revolution, or any whole number of revolutions.

In checking the accuracy of an ordinary lead-screw, the errors per foot are determined by the following method: The fixed anvil and the adjustable micrometer head are placed at one end of the lead-screw, and the micrometer spindle is adjusted to make contact with the anvil, as shown in Fig. 1. Next the lead-screw is revolved as many times as is necessary to move the engaging nut one foot, the number of turns depending, of course, upon the lead of the thread. The distance that the micrometer spindle has moved from the fixed anvil is then checked by using a standard end-measuring gage, as shown in Fig. 2. Whatever error there may be is readily determined by means of the micrometer. To secure greater refinement, as when checking the accuracy of screws that are more nearly in the precision class than ordinary lead-screws, standard gage-blocks are used in conjunction with a dial indicator, for taking the measure-

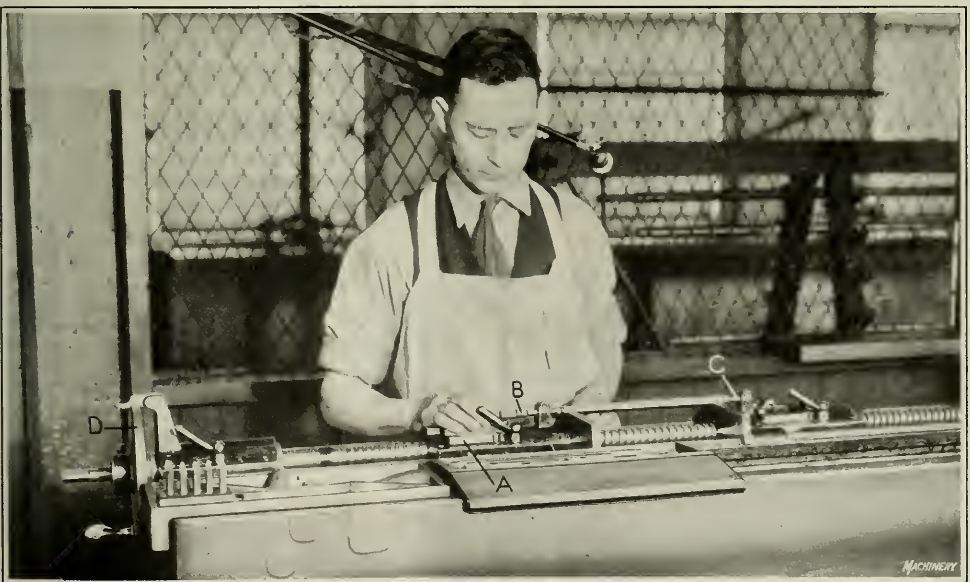

Fig. 2. Standard End-measuring Gage inserted between Anvil and Micrometer Spindle to show Lead Errors

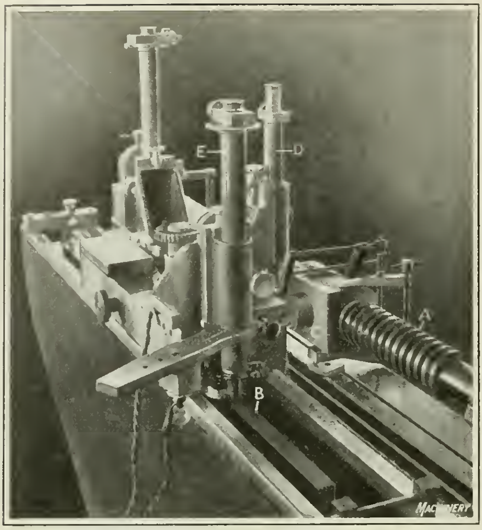

Fig. 3. Arrangement for testing Precision Screw by Direct Comparison with the Standard Bar of a Measuring Machine

ments, instead of an ordinary micrometer head and end-measuring gage.

Another method that has been employed when a very precise test is required is to check the accuracy of the screw by comparison with the standard bar of a precision graduating machine. Fig. 3 shows the machine equipped for this purpose. While this is a makeshift arrangement, any slight lead error in the screw may be readily determined in this way. The precision screw at *A* is compared with the standard bar at *B*. A small angle-plate carrying a polished plug, on which there is a very fine line, is clamped to the nut *C*. This plug is just beneath the microscope *D*, and it is a duplicate of the plugs inserted in measuring bar *B*. An index-plate is mounted on the end of the screw *A* to be tested. After adjusting nut *C* very carefully until it is square with the machine, microscope *D* is located over the plug attached to the nut, and microscope *E* is brought into position over one of the plugs in the measuring bar. The screw is then rotated a predetermined amount, after which the nut is again set square. The carriage carrying microscope *D* is also moved until the microscope is in alignment with the plug on the nut. Microscope *E* should then be in alignment with a plug on the measuring bar. If it is not, the difference is measured by the slide in the microscope, and this difference represents the error in the part of the screw that has been tested.

SETTING LATHE FOR TURNING TAPERS

By DUNCAN CAMPBELL

The method of setting a lathe for taper-turning operations described in the following has been used by the writer for several years. It has proved especially useful in boring the tapered holes in propellers and in turning the tapers on tail-shafts when fitting them to propellers. As an example of the application of this method, assume that it is required to bore out a tapered hole in a propeller and turn up the taper on a tail-shaft to fit the tapered hole in the propeller, the taper being 1 inch to the foot.

To set the compound rest to the proper angle for boring the tapered hole in the propeller, first scribe a circle on the face of the chuck or faceplate having a diameter of, say, 2 inches. Next scribe another circle with a diameter equal to that of the first circle plus one-half the taper per foot desired—or in this case, $2 + \frac{1}{2} = 2\frac{1}{2}$ inches. Two lines are next scribed on the upper and lower slide members of the compound rest at points *A* and *B*, as shown in the illustration. Now if it is simply a problem of boring a tapered hole in the propeller and turning the taper on the shaft to fit the hole, we can make the distance *C* between the two scribed lines *A* and *B* equal to 6 inches. However, if it is required that the taper be exactly 1 inch to the foot, it is necessary (theoretically at least) to make this dimension slightly greater than 6 inches. To be exact, the distance should be:

$$C = \sqrt{0.25^2 + 6^2} = 6.0052 \text{ inches}$$

It will be seen from this formula that for practical purposes dimension *C* in this instance can be taken as 6 inches. However, if the method is used for very steep tapers or if it is necessary that the taper be exact, it will be necessary to calculate *C* by the formula

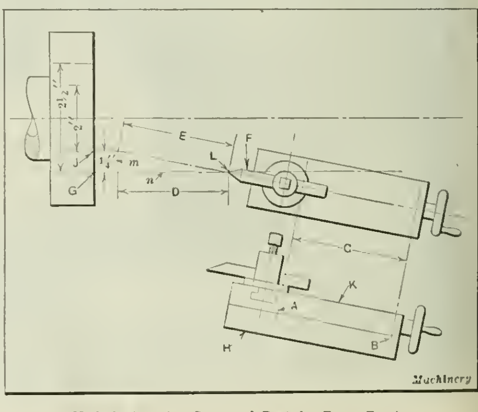
$$C = \sqrt{m^2 + n^2}$$

in which *m* equals one-half the difference between the diameters of the scribed circles on the faceplate and *n* equals 6 inches. The diameter of the larger circle scribed on the faceplate must, of course, equal the diameter of the smaller circle plus one-half the taper per foot desired, as previously stated.

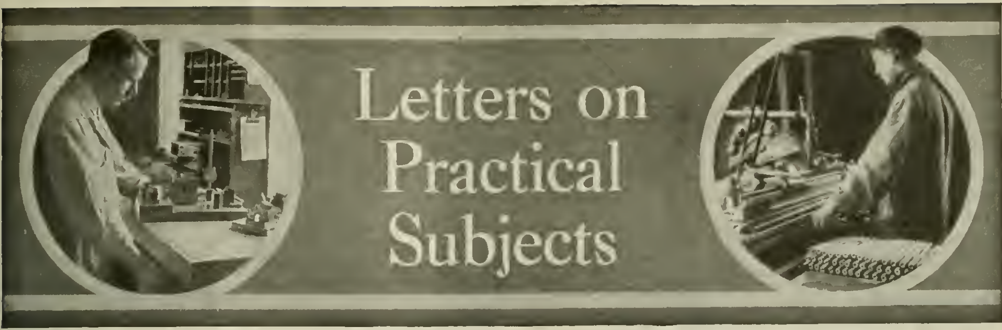
Next set the compound rest as nearly as possible to the proper angle for turning the required taper, and advance the carriage of the lathe until the point of a file or some other pointed instrument *F* comes in contact with the 2-inch circle at *J*. It is obvious that the point of *F* and the cutting point of the boring tool must be so set as to be at the same height as the center of the chuck or faceplate. Next adjust the upper slide member of the compound rest so that line *A* on the slide will be in line with line *B* on the lower member or slide base *H*. If the carriage is now brought forward and the point of *F* makes contact with the $2\frac{1}{2}$-inch circle at *G* it is evident that the slide is set at the proper angle for boring the hole. If this condition should not obtain, the angular position of the compound slide should be changed slightly until the required setting has been obtained.

Referring to the illustration, it will be clear that if *D* equals 6 inches and one-half the difference of the scribed circles equals $\frac{1}{4}$ inch, in order to turn a taper of 1 inch to the foot, slide *K* must advance a distance equal to dimension *E* from point *L* to make contact with the faceplate at *J* when the carriage is advanced. It is also clear that dimension *E* equals $\sqrt{m^2 \times n^2}$.

In turning the taper on the tail-shaft a 12-inch scale is clamped to the tailstock at right angles to the tailstock spindle and the graduations on the scale are used in the same manner as the circles scribed on the faceplate to determine the proper angular setting of the compound slide.



Method of setting Compound Rest for Taper Turning



CONVENIENT STOCK RECORDER

Inside every automobile speedometer there are two mileage registering units, one with three rows of figures and one with six. Speedometers are usually discarded because of some failure in the transmitting member, while the instrument itself is good for the life of several cars. The discarded speedometers may be obtained at garages and from junk dealers for a trifle and turned into useful shop appliances.

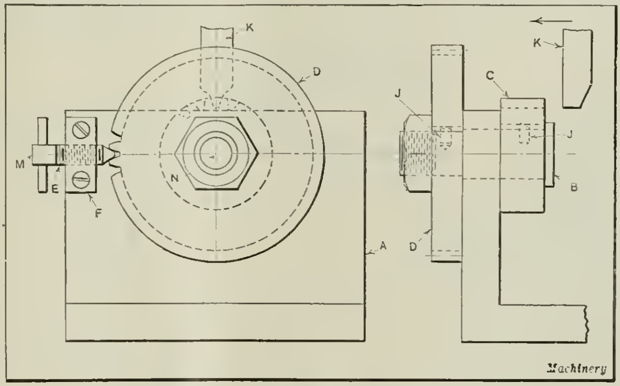
Records of incoming supplies, shipments going out, stock bins on which a perpetual inventory is kept, and inventory work in general all require the addition or subtraction of small numbers. When cards are used for this purpose, they become soiled and illegible. The mileage registering units from speedometers afford a convenient method of meeting these inventory requirements. The dials can be quickly turned to any number without becoming smirched by greasy fingers, and it is not necessary for the workman to use pencil and paper. It is a fundamental of tool design to reduce the number of "loose pieces" to a minimum; as applied to a stock bin with a perpetual inventory, this would mean that a registering unit should be attached to each bin.

There are, of course, various counters on the market (all operating the same as the mileage recording units of the speedometer) but they are larger and more expensive. The small or "trip" recording unit from a speedometer is particularly well suited for stock recording, and is so designed that it can readily be attached to any convenient post or to the wall.

Middletown, N. Y. DONALD A. HAMPSON

CUTTING GEARS WITH A SHAPER

A small pinion was required for a quick-repair job, and as there was no milling machine or gear-cutting machine available, it became necessary to provide some means of cutting the pinion teeth on a shaper. The way in which this was accomplished is described in the following. An angle-plate *A* was bored to receive the stud or shaft *B* on which the pinion blank *C* was mounted. A 40-tooth gear *D* belonging to a set of lathe change-gears was employed as an index-plate, and mounted on one end of shaft *B* as shown.



Fixture used in cutting Pinion Teeth on a Shaper

The end of index-pin *E* was turned to a conical shape and threaded to fit nut *F* at one setting in a lathe chuck. Nut *F* was attached to angle-plate *A* in such a position that it brought pin *E* into alignment with the center of shaft *B* on the line *MN*.

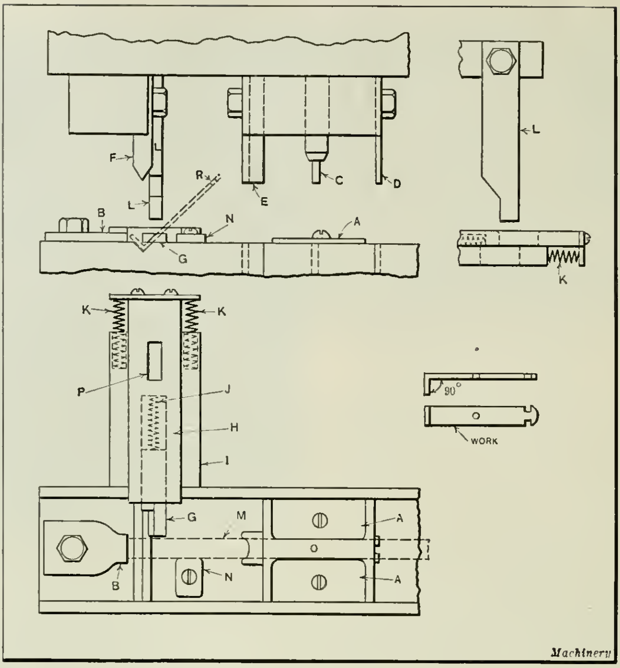
Gear *D* was indexed two teeth after each tooth space had been cut to depth, in order to obtain the correct spacing for the 20-tooth pinion being cut. The pins *J* in shaft *B* kept gear *D* and the pinion blank *C* in alignment. These pins were made a tight fit in the keyseats cut in the members that they held in alignment. The profile of tool *K* was ground to the correct form by using the teeth in the unbroken part of the original pinion as a gage or templet. The teeth were roughed nearly to size with a narrow tool before using the formed tool *K* for the finishing cut. The depth of the cut was determined by means of the graduated collar on the vertical feed-screw. The direction of the cutting stroke is indicated in the illustration by an arrow. A device similar to the one described was later used successfully in cutting ratchet teeth.

Algona, Iowa GEORGE WILSON

KNOCK-OUT FOR PUNCH-PRESS DIE

The accompanying illustration shows the construction of a punch-press die equipped with a knock-out mechanism. In the upper left-hand corner is shown a front elevation of the punch and die, while directly below is a plan view of the die. A side view of bar *L* which actuates the knock-out mechanism is shown in the upper right-hand corner. The work is formed from soft iron stock 0.250 inch wide by 0.060 inch thick. The stock is fed from the right-hand side of the die, between the guide plates *A* and against the stop *B*. When the ram descends, the stock is pierced by the punches *C* and *D* and cut off by the punch *E* while the 90-degree bend is formed by the punch *F*. As the ram ascends, the work is thrown out by the knock-out plunger *G*.

The interesting point in this die is the knock-out mechanism, which is shown with the ram in its extreme upper position. The knock-out plunger *G* slides in another plunger *H*. Plunger *H*, in turn, slides in a groove in an angle-piece *I* which is carried on the back of the die-bolster.



Punch-press Die equipped with a Knock-out Mechanism

Plunger *G* is held in its extreme forward position by the spring *J*, while plunger *H* is held in its extreme backward position by the springs *K*. Each of these plungers carries a stop-pin (not shown) which limits its motion. The bar *L* has a cam action on the downward stroke, imparting the necessary motion to plunger *H* by passing through the oblong hole *P*. The dotted lines at *M* show the position of the stock when the punch begins its descent. It will be seen by referring to the illustration that plunger *G* is so located that it just clears the edge of the stock.

When the ram has descended until the forming punch *F* comes into contact with the stock *M*, the punches *E*, *C*, and *D* will have just passed through the stock. The cam surface of the bar *L*, in its downward travel engages the forward edge of the oblong hole in the plunger *H*, causing it to move forward a distance equal to the throw of the cam surface. As plunger *G* is also carried on plunger *H*, it also has a tendency to move forward, but is prevented from doing so by coming into contact with the edge of the stock *M*, as shown.

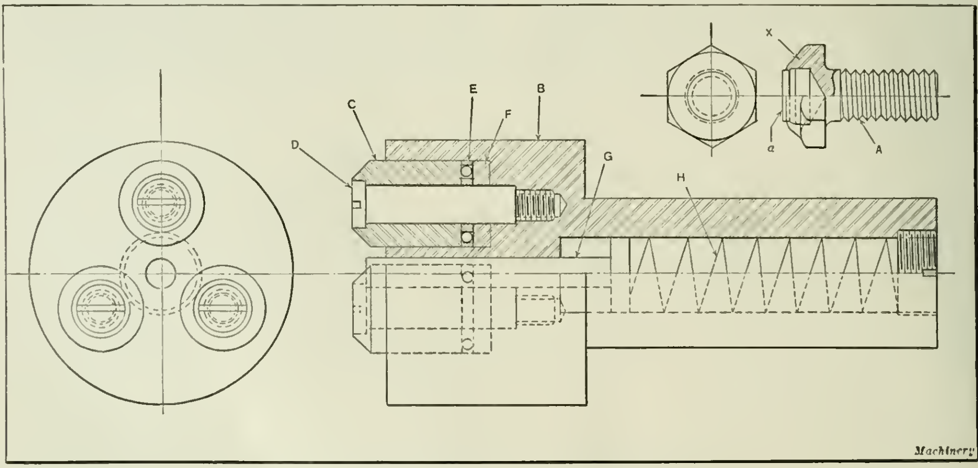
The stock *M* is held in position by the guide plates *A* and the stop *N*. In this position, the spring *J* is compressed, and pressure is exerted on the stock through the plunger *G*. Continued downward travel of the ram brings the forming punch *F* into operation, with the result that the stock is raised on one end so that it clears the stop *N*, as shown by the dotted lines at *R*, and is bent to the shape indicated. The pressure of the forming punch *F* on the stock is sufficient to overcome the action of the spring plunger *G* on the edge of the stock.

As soon as the ram starts on its return stroke, the pressure of the punch *F* on the stock is released, and the spring *J* actuates the plunger *G*, throwing the work clear of the die. The springs *K* then return the plunger *H* to its original position. When the press is running at a speed of 150 revolutions per minute, which is the speed regularly employed with this die, the work is thrown clear of the press bed, and into a hopper placed in a convenient position to receive it.

Philadelphia, Pa. R. H. Kasper

ROLLING TOOL FOR ASSEMBLING PLUG IN SCREW HEAD

The valve thrust screw shown at *A* has a hardened steel tapered plug *a* inserted in a drilled hole in its head, where it is held in place by peening or riveting over the edge *X* of the screw. This riveting operation was originally accomplished by means of a rivet-set and hammer, but the heavy blows necessary cracked many of the hardened plugs, thus causing the entire piece to be scrapped. To overcome this



Tool used in assembling Hardened Plug in Head of Valve Thrust Screw difficulty, the tool shown was devised which rolls the metal instead of striking it.

The tool consists of a machine steel body B, turned to fit the machine at one end and bored to receive the three hardened tool steel rollers C in the other end. The rollers C are held in place by screws D, and the feed thrust on the rollers is taken care of by three small ball thrust bearings E which, in turn, transmit the thrust to the hardened washers F. A plunger G, actuated by spring H, holds the valve thrust plug a in place while rolling over the edge X.

The tool operates as follows: After the valve thrust screw and plug are chucked, the machine is started and the tool fed down on the screw. The plunger G strikes the plug and holds it in position before the rollers C begin to operate. As the tool is fed farther the rollers strike the edge X, and roll it down, thus completing the operation. The chamfer on the ends of the rollers C in this case was made 45 degrees.

Chicago, Ill. HAROLD A. PETERS

INDEXING FIXTURES FOR HAND MILLING MACHINE

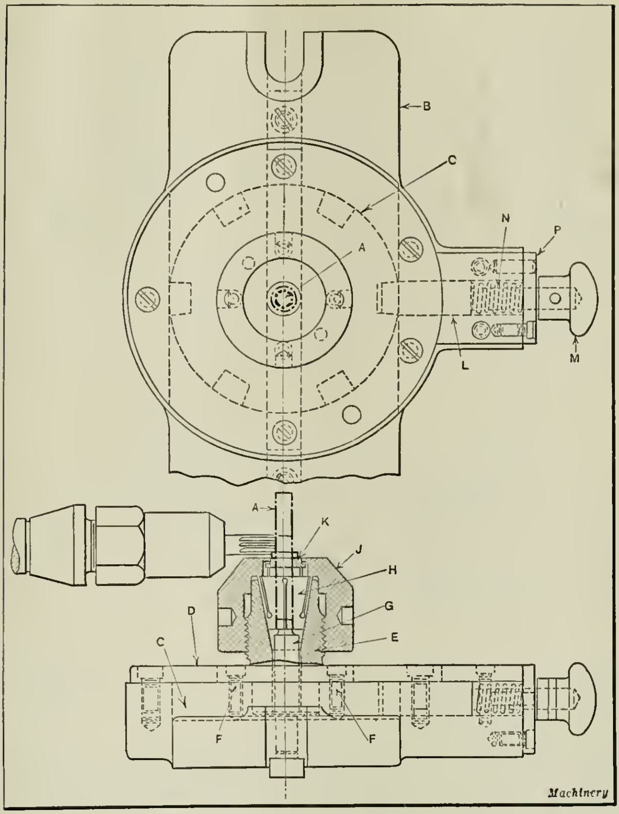


Fig. 1. Indexing Fixture for milling Hexagonal Section

An indexing fixture for use on a hand milling machine is shown in Fig. 1. This fixture is provided with a vertical chuck designed to hold the work shown by dot-and-dash lines at A, which is required to have flats milled on six sides to form a hexagonal section as illustrated in the plan view.

The base B of the fixture carries the index-plate C which is retained by the plate D. The spindle nose E is a separate piece and is fastened to the index-plate C by means of screws F. The spindle nose carries the work-locating stop-pin G. The spring collet H clamps the work in place when cap J is screwed down on the washer K. The indexing plunger L is provided with a knob M and is forced into the slightly tapered indexing slots by the action of spring N. Spring N is retained in place by a plate P which is fastened to the plunger base as illustrated.

The indexing fixture shown in Fig. 2 is for milling cross-slots in the head of the bolt shown by heavy dot-and-dash lines at A. This fixture is similar in design to the one illustrated in Fig. 1. The index-plunger in this case, however, enters indexing holes in the spindle, and therefore requires no additional index-plate.

Waynesboro, Pa. D. A. NEVIN

FORMING DIE AND ANGULAR SHEARING PUNCH

A die of rather unusual construction containing a forming punch and die, in combination with a shear punch, and mechanism for operating it is shown in Fig. 1. This die is used on a press having a so-called "double action," inasmuch

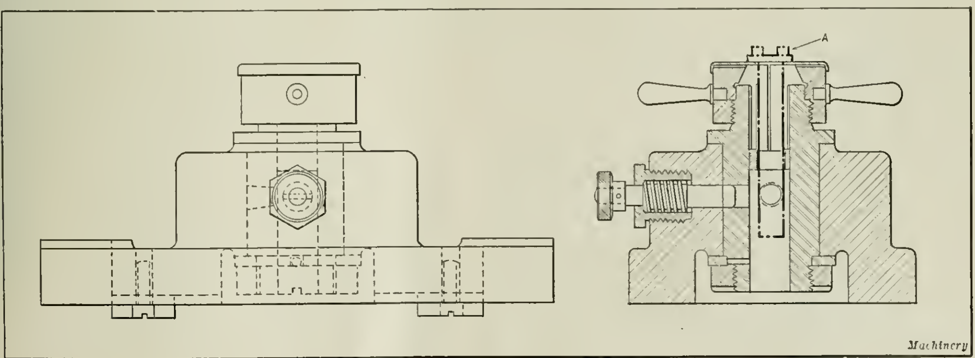

Fig. 2. Fixture used in milling Cross-slots in Bolt Head

as the forming punch must come down and form the work, after which it dwells while the shearing punch is operated. A detail view of the work is shown at the left. Fig. 2 shows some of the details used in the construction of this die; the same reference letters are used for these parts as in Fig. 1.

Referring to Fig. 1, the forming punch *A* is held in place in holder *B* by set-screw *C*. A screw *D* with a brass shoe in front of it prevents screw *C* from working loose under the continual jar of the press. At *E* is an adjustable punch against which the formed part is sheared when the die is in the closed position. This punch is backed up by the screw shown at *F*. The die over which the work is formed is contained in a cast-iron die bed *G*, the formed die being illustrated at *H*, and the shearing punch at *J*. Screws hold the formed die in place as shown. At *K* is a steel block held in place by two screws *L*. On the top of this block is a stripper plate, the stock from which the work is made being fed through a cut-out or slot in this plate. The stock is cut by the punch *M* as it descends, being sheared at point *X*.

As the forming punch descends the work is bent over the forming die and is held there while shearing punch *J*, through the medium of plunger *P* is forced out by the rocker *Q*. Rocker *Q* is pushed down by a lever at the side of the press, which is operated by an eccentric. In this connection it should be borne in mind that the press is of the cam-operated type, which allows the forming punch to dwell a short time while the shearing punch is operated by the eccentric. The spring *R* keeps the shearing punch back by acting against the collar *S* which is pinned to the punch. The spring *T* keeps the rocker and intermediate piece in contact with the operating lever which has but a slight action and is guided in block *U*.

This die proved an economical means of handling the work, as the diagonal shearing is an operation which would take much time if performed separately. F. SERVER

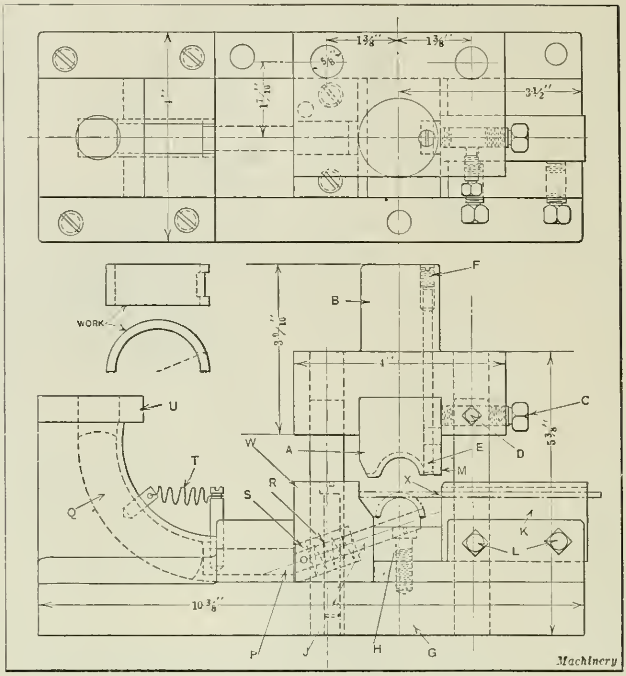

Fig. 1. Forming Die equipped with Angular Shearing Punch

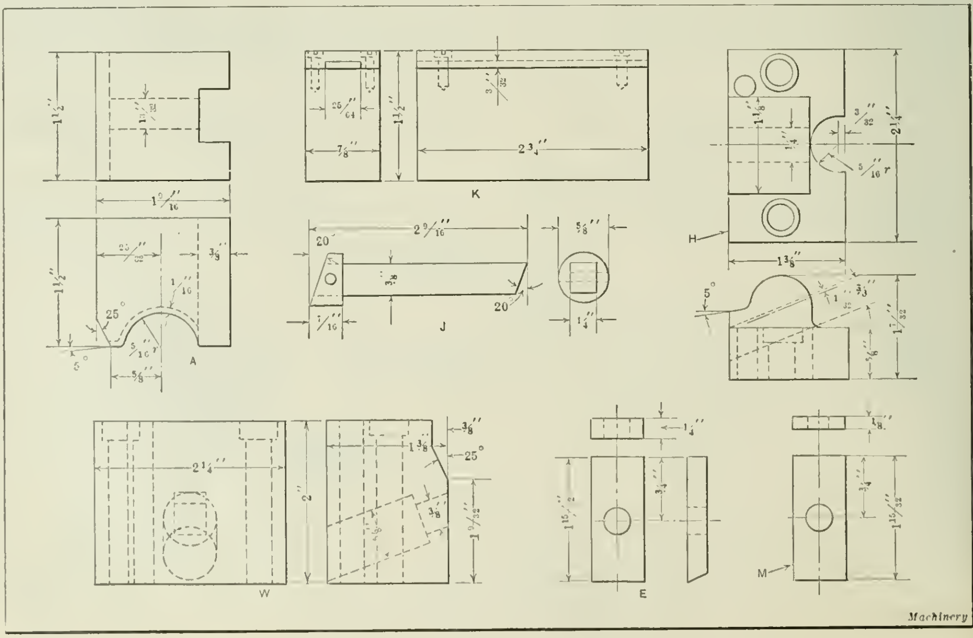

Fig. 2. Details of the Shearing Punch illustrated in Fig. 1

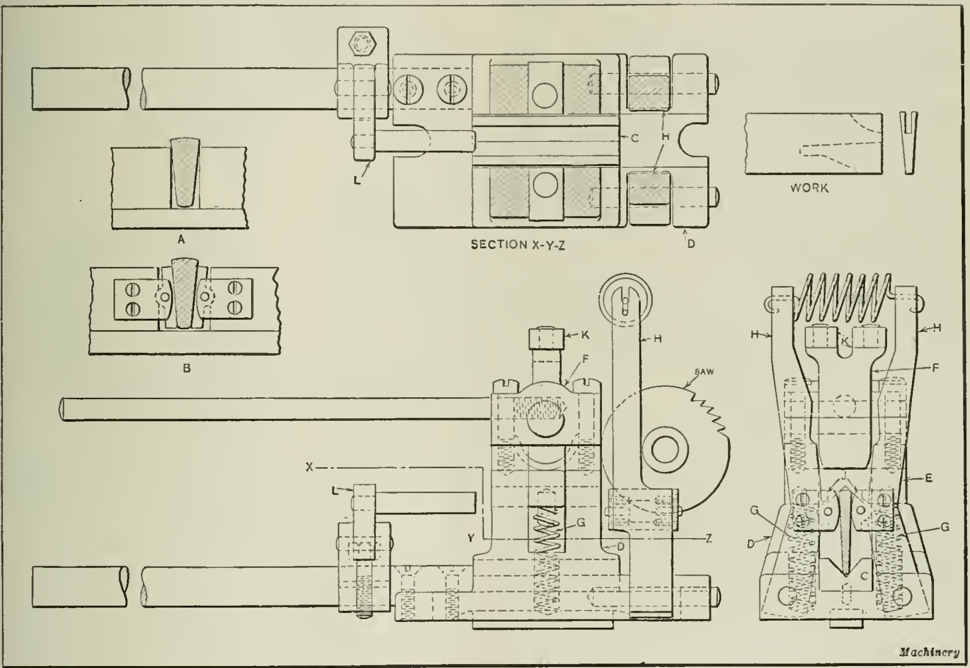
SLOTTING FIXTURE FOR COMMUTATOR SEGMENTS

The copper bars or segments in a commutator are slotted at one end to accommodate the leads used in soldering the armature windings. The detail view in the upper right-hand corner of the accompanying illustration clearly shows the construction. Ordinary milling machine vises are usually employed for holding the work while slotting, but these require a lot of adjustment to suit the great variety of widths and sectional shapes that have to be handled.

The varying angularity of these wedge-shaped sections makes it inadvisable to construct tapered vise jaws to conform to each change in shape, and so ordinary straight jaws are extensively used. These jaws pinch the bars in the manner indicated at *A*, causing them to be indented. An excessive amount of pressure is required to keep the bars in place by the use of jaws of this type, so that often the vises break or the threads in the nuts are stripped from the continuous tightening of the crank-handle. Not only is this means of holding unsatisfactory, but it is also a laborious task to perform the work by the use of a vise of this kind. Adjustable jaws like those illustrated at *B* may be used on milling machine vises, but these have a tendency to pinch the work and cause the sides of the slot to bind on the saw.

Owing to the objections to the use of milling machine vises equipped with either standard or adjustable jaws, a special fixture was designed for clamping these segments, the construction of which is shown in the illustration. This consists of a cast-iron base *D* which is attached to the table of a bench milling machine, and which carries the clamping arrangement. Its advantage is that it can accommodate various sizes of segments and that it is quick-acting. The position of the work is indicated in section in the end view, from which it will be seen that the bars are located vertically and clamped between two V-blocks, *C* at the bottom and *E* at the top. Block *C* is a stationary member located in a slot in the base, while the upper V-block *E* exerts pressure on the top of the work through an eccentric cam *F*, which is operated by a long lever. The base has a wide slot to accommodate this cam, and it is supported by trunnions and held in place by bearing caps.

The under side of V-block *E* carries two pins, which anchor the top ends of the two coil springs *G*, located in the base of the fixture. The purpose of these two springs is to exert pressure against the top V-block, keeping it in contact with the cam. Provision is made in this clamping device for exerting a light pressure on the work while the slot is being cut, thus preventing the walls from spreading, which is quite likely to occur, especially on thin bars. For this purpose two levers *H* carry a pair of swivel jaws *J* at their lower ends. The pressure of these jaws on the work is removed as soon as the clamping mechanism is released, by means of the same cam *F* used for clamping. In releasing the upper V-block by means of the long lever, cam *F* is revolved so that the rollers *K* operate against the lower surfaces of the levers *H* and force them apart. These rollers are integral parts of the cam.



Quick-acting Clamping Device for Holding Commutator Bars

The weight of the long lever by means of which the cam is operated is sufficient to exert clamping pressure enough to hold the bars rigidly during the slotting process. Segments of various sizes can be handled in this fixture without requiring adjustment and with the assurance that they will be located centrally and vertically. When heavy bars are being slotted, the compression spring connecting the side levers *H*, by means of which the pressure is exerted against the bars, may be removed and the levers omitted. When bars of varying widths are to be slotted, V-block *C* may be shimmed up if necessary. An adjustable stop with a pivot arm *L* is employed to suit varying lengths of bars. This arm may be easily swung back so that the bars can be inserted without interference. This device has been in constant use for two years, and as a result of the speed with which it can be operated the cost of machining the segments has been considerably reduced.

East Orange, N. J. JOHN E. UNGER

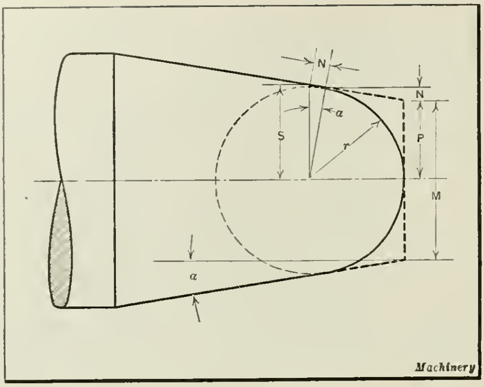


Diagram for finding Diameter at End of Tapered Rod

DETERMINING THE DIAMETER AT THE END OF A TAPERED ROD

When the tapered end of a rod has been machined to a semi-spherical form, as shown in the accompanying illustration, it is sometimes desirable to determine the original diameter M at the end of the rod. The following solution to this problem may be of interest to tool designers and toolmakers. Referring to the accompanying illustration, the known dimensions are:

a = angle of taper at end of rod; and

r = radius at rounded end.

With these values known, it is required to find M, or in other words, to find the original diameter at the end of the piece before forming. Now by trigonometry,

$$N = r \tan a \quad \text{and} \quad S = r \sec a$$

$$P = S - N$$

Substituting,

$$P = r \sec a - r \tan a = r (\sec a - \tan a)$$

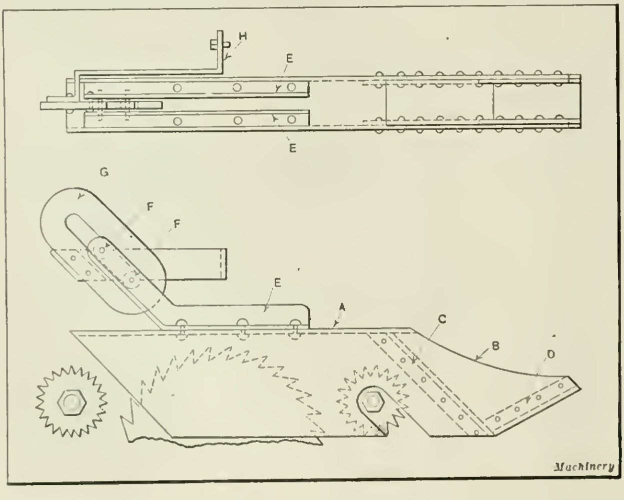
Then

$$M = 2P = 2r (\sec a - \tan a)$$

Flint, Mich. W. G. HOLMES

GUARD FOR CIRCULAR SAW

A guard for a power-fed circular saw that will cover both the saw and the feed-wheels properly is shown in the accompanying illustration. It consists of a hood or guard A and



Guard for Circular Saw

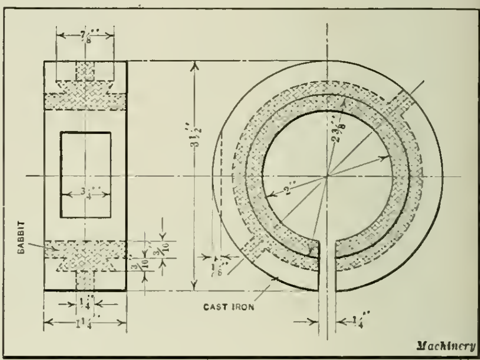
a nose-piece B, both of which are made of heavy sheet-iron stock. The two sides and the top are in one piece with the division plates C and D, which are riveted to the sides as shown.

The angle-irons E are equipped with anti-friction rollers F, which fit loosely in a slot in plate G. Plate G is fastened to the bar H, which, in turn, is bolted to the frame that carries the feed-rolls. As the slot in plate G is at an angle of 45 degrees with the top of the saw table, the guard will slide upward at this angle when a board is forced under the nose piece. When the guard is to be removed, it is only necessary to take out the two bolts which fasten bracket H to the feed-roll frame. This guard has proved very satisfactory, and in addition to protecting the operator from the saw, it prevents sawdust or small splinters from getting into his eyes.

Kenosha, Wis. M. E. DUGGAN

BUSHING FOR STEADYREST

The writer read with interest the description of a steadyrest bushing on page 566 of March MACHINERY. Another method of preventing the marring of ground or polished work and one which the writer believes would be more economical is to employ brass steadyrest jaws. In addition to



Babbitt-lined Bushing for Steadyrest

being less expensive, jaws of this type would give a wider range of adjustment.

A compression collar bushing for use in a steadyrest when it is required to support splined shafts or shafts having keyways is shown in the illustration. The particular bushing here illustrated is designed to support shafts approximately 2 inches in diameter, and is made from a piece of scrap cast iron lined with babbitt metal. The collar is dovetailed and drilled in such a manner as to retain the babbitt under the severe usage to which equipment of this nature is usually subjected. It will be noted by referring to the illustration that there is a flat on the top of the collar. This provision is made so that the top steadyrest jaw can be tightened on this flat spot, and thus prevent the bushing from turning in the steadyrest.

If the bore of the bushing is worn, the collar can be rebored to the next larger size, or if desired, the babbitt can be melted and the collar rebabbitted. A mandrel or bushing that will give the correct bore diameter is set on a cast-iron plate to form the mold used in rebabbitting the collar. Replacements of this kind have proved satisfactory and are inexpensive.

Cincinnati, Ohio FRANK C. LANG

Do's and Don'ts on the Care of Hobs

By HARRY E. HARRIS, President, Harris Engineering Co., Bridgeport, Conn.

HOBS are expensive tools when the initial cost alone is considered. They must be carefully designed with regard to what they are to produce, and must be accurately made by skilled mechanics with costly equipment. It is therefore impossible to produce a good hob without a considerable expenditure. In spite of this high initial cost, if properly used and cared for, hobs are, in point of quality and quantity of work produced, among the most economical tools used in the manufacture of gears and other parts that permit of hobbing. This economy is due to the fact that the hobbing operation is continuous, there being no necessity of interruption for table return or indexing. The purpose of this article is to give a number of points on the care and upkeep of hobs, so that their primary high-cost may be distributed over the maximum amount of work. The rules are simple and brief, and should be followed by those responsible in any way for hobs and hobbing operations.

Hobs should be checked for tooth clearance, as the clearance often varies on teeth of the same hob due to faults of the master forming cam on the machine in which the clearance is cut or to distortion in hardening. If the amount of clearance varies, the cutting edges will assume different heights from the center of the hob when the faces are uniformly ground in resharpening. This will cause some teeth to take heavier chips than others, resulting in marks on the work.

Rules Concerning New Hobs

First, care should be taken to make sure that only good hobs are purchased, because a good hob is the only one that it really pays to use. If a hob is inaccurate or partly distorted, expensive work on individual teeth, as for example grinding the faces different amounts or otherwise, will not make the hob good, and such practice, which is merely sending good money after bad, should be discontinued. Good hobs are readily obtainable, and there is no excuse for accepting and tinkering with defective hobs.

The following rules should be carefully followed by the user of hobs:

1. New hobs should be checked for concentricity while mounted on an arbor placed between centers.

2. The clamping faces should be checked for squareness; if these faces are not square with the hole, the hob will spring the arbor on which it is mounted when in the machine.

3. The hole should be round and to size; if it is otherwise, the hob will rotate eccentrically to some extent.

4. Hobs having the tooth form and clearance ground are preferable, even on rough work, because of the longer life of cutting edges. However, if ground hobs are not used, those that have not been smoothly formed or have been pitted or scaled in hardening should be rejected.

5. Each tooth should be tested on the face and heel for hardness by employing a file or some other recognized method, but the cutting edge or clearance should not be filed, because such practice may injure the hob.

6. The faces of the teeth should be inspected to see that they are ground smoothly and that the cutting edges are really sharp and have not merely been polished bright with an elastic wheel after hardening while holding the hob by hand. The least rounding of the cutting edges causes the hob to cut hard and tear, so that it will not stand up long.

7. Hobs should be rejected when the face of the teeth is at all convex or when this surface has a negative rake, that is, when the face is tipped back from a radial line extending to the center of the hob. In fact, preference should be given to hobs having the faces slightly concave.

8. For best cutting results as regards speed of production, life of cutting edges, and smoothness of work, hobs should be so designed that the teeth can be given a rake or hook; that is, they should have the face ground under-cut from the cutting edge at from 7 to 15 degrees relative to a radial line. Such hobs cut easier, faster, and smoother, and last longer than when each tooth face is radial.

9. The gashes or flutes should not be so narrow that an insufficient chip space between the heel of one tooth and the face of the succeeding tooth will permit the hob to become clogged up with chips. Such clogging with a narrow-fluted hob is one reason that many new hobs work poorly, as compared with old hobs, which, by repeated grindings, have had the flutes widened and thus have adequate room for lubricant and chips. Hobs with fewer and wider spaced teeth and fewer flutes give far better results than hobs with more teeth which are closely spaced.

10. Each tooth should be checked for depth, form, and width by the use of templets, or a bevel gage or protractor and a depth gage.

11. The hob lead should be checked; this may be done by mounting the hob between the centers of a lathe having a good lead-screw geared for the proper hob lead and then using an indicator carried on the toolpost.

12. It is important that the gashes or flutes be properly spaced, because a hob with inaccurately spaced flutes cannot be made to cut satisfactorily. There is no excuse for inaccurate indexing of a hob when it is being made, and so it may be assumed, in instances where the flute spacing is inaccurate, either that the operator of the machine on which the hob was produced made an error in his settings or else that the hob has been distorted in hardening.

13. Hobs should be checked for tooth clearance, as this often varies on teeth of the same hob due to faults of the master forming cam on the machine in which the clearance was cut or to distortion in hardening. If the amount of clearance varies, the cutting edges will assume different heights from the center of the hob when the faces are uniformly ground in resharpening. This will cause some teeth to take heavier chips than others, and the hob will be used up faster and will make marks on the work. A hob may be checked for tooth clearance by clamping an arbor in a V-block placed on a surface plate, mounting the hob on the arbor and then rotating the face of each tooth in succession against a horizontal spring stop. As each face is brought against the stop, the amount of clearance can be measured near the tooth heel by means of an indicator in a height gage, located at a fixed distance from the end of the stop.

Caring for Hobs in Use

Care should be taken to get as much work as possible from hobs. They should not be wasted by abuse or misuse; unnecessary shut-downs of machines while waiting for hobs to be resharpened should be eliminated, and resharpening should be accurately and expeditiously done. More time and money are lost daily from neglect of the foregoing points than is generally realized. If the following rules are observed in the use of hobs, these tools will last longer and there will be less non-productive time, higher production and lower upkeep cost.

14. A hob should never be put in a machine until it has been carefully inspected, as outlined in the preceding rules.

15. A hob should be examined each time it is used, to make sure that all cutting edges are sharp. One dull tooth is sufficient to cause hard cutting, a poor finish, and inaccurate results. Furthermore, as the dull tooth is invariably the highest one, it has the most work to do and speedily becomes excessively dull or "dubbed off," so that it may be necessary to grind the faces of all teeth 1/8 inch or more before they are satisfactory. As from 0.005 to 0.010 inch only, at the most, should be removed from the faces at a sharpening, this would result in a great loss of time and money.

16. When sharpening a hob, the grinding should never be forced. Light, quick cuts should be taken with a high-speed soft, coarse wheel. Many hobs are burnt on their cutting edges through using hard, slow running wheels or because the hob is crowded against the wheel in trying to grind it quickly. Not only may the same amount of stock be removed by light, quick cuts in the same time, but the effect of burning, even if the hob shows no discoloration, is a softening of the cutting edges, which causes them to dull rapidly and "dub off." Then at each successive grinding, a greater amount of tooth face must be ground off, and as the operator forces the grinding a little more each time, the hob is rapidly used up or cast aside as worthless.

17. Hobs should always be ground under flooded lubrication for the same reason that light, quick cuts should be taken with a soft wheel running at a high speed. The stream of lubricant should be directed at the grinding contact.

18. In sharpening a hob it is advisable to make sure that the grinding wheel will produce a smooth face. Rough scratchy grinding means fine saw-tooth cutting edges, which crumble and lose their keenness. If the proper facilities and the right wheel are not obtainable, apply an India oilstone by hand after the grinding operation, to produce fine sharp edges.

(Careful attention to Rules 16, 17 and 18 will effectively prevent burning and result in smooth surfaces and finer, keener, and more durable cutting edges.)

19. In sharpening hobs having radial faces, care should be taken to see that the teeth are not given a negative rake, as mentioned in Rule 7. In attempting to sharpen hob faces to radial lines, it is difficult to prevent this from happening, because if the cutting face of the wheel is set radial to the center of the hob, that part of the wheel grinding at the bottom of the teeth wears away much faster than the part grinding at the tops, because it has more metal to remove. The result will be a negative rake. To overcome this effect, the wheel should be set over so as to tend to under-cut or give a rake to the tooth faces. Then, after the hob is ground, the tooth faces will be approximately radial from top to bottom and slightly concave due to the wear of the wheel. The amount that the wheel should be set over varies, depending on the wheel, hob, and the amount to be ground from the latter, but the set-over may be readily determined from observation.

20. It has been proved beyond question that hobs should be under-cut, that is, that they should have the front face of the teeth slanting from top to bottom at least 8 degrees back from a radial line. The cutting angle on this style hob is generally stamped on one end of the tool, and care should be taken to maintain this angle. The cutting face of the wheel should be carefully set in resharpening, and the hob checked after such an operation. It is often possible to grind radial-tooth hobs so that the face will have a cutting angle of a few degrees. This will improve the cutting action of the hob without affecting the developed contour of the work or the depth of cut sufficiently to be objectionable.

21. It is poor practice to grind back and forth through a flute more than once at a time; the better method is to index to the next flute and grind back and forth through that flute and so on, all around the hob. The practice of grinding back and forth through a flute many times in succession is unsatisfactory, although often followed in grinding hobs with attachments or by makeshift methods. It should be avoided for the following reasons: First, because the teeth become so hot that they are burnt; second, the wheel wears and changes its shape, with the result that the cutting faces of the hob teeth are at different angles; and, finally, the spacing of the flutes becomes irregular.

22. A hob should be ground until all the teeth are sharp, because one dull tooth will cause trouble.

Do not grind back and forth through a flute more than once at a time, but rather index to the next flute and grind back and forth through that flute and so on, all around the hob. The practice of grinding back and forth through a flute many times in succession is unsatisfactory, although often followed in grinding hobs with attachments or by makeshift methods. The reason this practice should be avoided is that, first, the teeth become so hot that they are burnt; second, the wheel wears and changes its shape, with the result that the cutting faces of the teeth are at different angles; and, third, the spacing of the flutes is irregular.

23. A hob should not be allowed to remain in a machine after it becomes dull; it should be sharpened immediately. The unsatisfactory results obtained with a dull hob have previously been mentioned under Rule 15.

24. The hobbing machine should be kept running at the maximum feed and speed for the job.

25. The life of a hob must not be judged by the number of days it lasts in production, but by the number of parts or inches of metal that have been cut. Furthermore, the need for sharpening must not be judged by the number of hours run, but by the number of parts or inches of metal cut between grindings.

26. Hobs should be changed and sharpened frequently; thus less metal is required to be ground off each time. The production rate can then be materially increased by speeding up the machine. Sharp hobs will easily give double the production obtained with dull hobs.

27. The resharpening of hobs should be made easy. The reason that much work is spoiled by the use of dull hobs is that sharpening, especially of spiral-fluted hobs, is usually a difficult operation in a shop not properly equipped for this purpose. The result is that dull hobs accumulate and are often put away and used again without sharpening. Then, when a set-up is made at last to grind the dull hobs, the work is likely to be rushed through, wrong wheels, speeds and feeds being used and the hobs ground dry. Even with the most skilled grinding machine operator, results under such conditions will be poor. A machine for grinding hobs properly should always be ready to receive a job.

28. An individual record should be kept on a suitable card of the work produced by each hob. This will make it possible to compare hobs made from different brands of steel, subjected to different heat-treatments or purchased from different concerns. The results of ground hobs may also be compared with unground hobs.

29. Hobs should be kept oiled or greased when not in use, because a rusty cutting edge will not be sharp.

30. Hobs should not be stored loose on a shelf or in a box. Their edges are easily damaged in this way and they are likely to chip and nick one another in being shuffled about. Then, too, they may roll off a shelf and drop on a metal base or cement floor. A board provided with wooden pegs fitting the holes of the hobs is an excellent means of storing these tools. An individual peg board, having the name and number of the hob for which it is intended, is also satisfactory for storing hobs in a tool-room.

The British Metal-working Industries

From MACHINERY'S Special Correspondent

London, June 14

EXPERIENCE in all quarters of the engineering industry points definitely to the fact that trade is at last gathering momentum. Even the protracted labor dispute of the last two and a half months has not been sufficient to counteract the tendency toward general improvement.

The Machine Tool Trade

The machine tool trade is moving very slowly with the general trade improvement. There is a more decided tendency to buy, and the stocks of manufacturers are being slowly reduced. The machine tool trade has perhaps suffered more by the lock-out than the majority of trades, since the proportion of skilled workmen is very high in the general run of British machine tool shops.

Very little stability exists in prices of machine tools, and quotations from several firms for substantially the same machines frequently show a wide range of prices. Selling prices are controlled, not so much by the cost of production, as by the great necessity of turning money over and reducing stocks. The influence of the second-hand market continues to be felt, although the war surplus has been substantially reduced, and the machines have passed largely into the hands of the dealers instead of being put into production.

Overseas Trade in Machine Tools

Inquiry for machine tools from other countries is excellent and of a much better tone. The export and import returns for machine tools showed a small drop from the figures reached during the previous month. In tonnage, exports fell from 1447 to 1421 and in value from £184,776, to £171,612; import tonnage was reduced from 343 to 266, the value being £30,779 instead of £37,338. The value per ton of imports showed a tendency to rise after the fall over several months; the value per ton of exports continues the tendency to fall shown during the last twelve months. The imports and exports are now approximately equal in value —about £115 to £120 per ton.

Figures show that Germany is now the most important exporter into this country. During April Germany sent 141 tons of the 266 tons of machine tools imported; the amount was divided among all classes of machine tools, although drilling machines and lathes predominated. America sent 54 tons, principally grinding machines and special machines, but practically none of the classes in which Germany led. Against this, it must be realized that whereas America's contribution had a value of £12,000, Germany's much larger contribution had a value of only £8000. These figures are significant in view of the fact that Germany's contribution to the British market is now in process of growth.

New Machine Tools

A few new designs of machine tools have appeared during the last few weeks. These include radial drilling machines by Kitchen and Wade, of Halifax. A prominent feature of these machines is an auxiliary spindle for tapping purposes. The extra spindle runs at one-third the speed of the main drill spindle and can be arranged for driving right- or left-hand taps. The same firm has also introduced a line of girder type radial drilling machines.

An interesting pipe flange facing and turning machine has been developed by Haighs (Oldham) Ltd., Oldham. It is particularly suitable for machining simultaneously the three flanges of large pipe fittings such as tees, etc. Producer plant piping and many types of valves also can be conveniently faced on this machine. It is built on the lines of a lathe with heads at each end of the bed, while another bed carries a third head the spindle of which is driven in unison with the other two, and is arranged at right angles to the main bed. The work is held stationary during machining, and is gripped in two self-centering vises that can be moved to convenient positions along the bed.

The spindles carry faceplates on which are mounted facing and boring tools. The facing tools are carried on cross-slides on the faceplates and these enable facing cuts to be taken. The feed is automatic through a "picking gear" or "star wheel" operated at each revolution of the spindle. For turning the flange diameters or for boring, the heads are fed along the bed. The machine accommodates pipes up to 9 feet in length by 20 inches in diameter; one 10-inch and two 14-inch flanges can be faced and turned in two hours.

The Automobile Industry

Automobile manufacturers maintain their strong position. Demand has exceeded all expectations, and buyers are pressing for prompt delivery. There is a large accumulation of orders which though taken early in the season, are still waiting to be filled, and it is imperative that there should be no further hindrance to production.

Owing to high taxation and similar causes, particular attention has been paid to the development of automobiles which, while giving ample power for ordinary requirements, are rated sufficiently low to come within the scope of the lower grade of taxation. Cars that fulfill these requirements are about 10 horsepower, and besides being subject to a relatively low tax they can be obtained at a reasonable price and are economical to run.

So strongly is it felt that the light automobile is assured of an exceptionally bright future that, after carefully considering the question, several prominent firms have decided upon an increased output and are arranging to expand their plants accordingly. In one factory in the Coventry district, such extensions are already in progress, and when completed will provide for a threefold increase in the output.

Iron and Steel Trades and Material Prices

In the iron and steel trades there is a quiet but steady demand. Conditions in the home trade have not materially altered, and business has been held in check by the engineering dispute. However, although there is but little buying, consumers are keeping in touch with the market in anticipation of the demand arising as soon as the dispute is settled.

Foreign demands for British materials continue to increase, and for this reason steel makers are able to maintain their recent rate of output. India, Siam, South America, and South Africa are in the market for large quantities of railway equipment, and it is thought that a good share of these orders will come to this country, provided suitable credits can be arranged. The situation in the pig iron market is still encouraging, and buyers of both hematite and foundry irons may expect an advance in prices almost immediately. American buying of British iron has not developed to the extent that was anticipated, but the over-seas demand generally is good. Germany is still a prominent buyer and some sales in Czecho-Slovakia have recently been made.

Metal prices have shown little or no fluctuation during the last two months. Finished steel in the form of round bars remains at £9 15s to £10 10s per ton, while finished iron as crown bars sells at £11 to £12 10s per ton. Pig iron varies from £3 12s 6d to £4 10s, according to grade.

The Machine Tool Industry

THERE is steady improvement in the machine tool industry. New orders now average between 20 and 25 per cent of the peak business. Six firms out of seventy-seven state that their business is more than 50 per cent of peak business, which may well be considered normal or above normal. About thirty firms out of the seventy-seven are doing a business that may be considered from one-third to one-half normal or better. Stocks have been materially reduced within the last two months, and it is only in a few instances that machine tool manufacturers now say there is no improvement in their business. Practically all the shops that were shut down during the most severe period of the depression are now running to some extent, and some of the largest report sales averaging 50 per cent of what is considered normal. Such statements as, "we have had more business in the last six weeks than we had in the previous six months," or "we have had twice as much business since the first of January as we had during all last year" are not unusual.

On account of working off the stocks on hand, the shops as yet do not run in proportion to orders received, but the assembling departments of several plants are working to a satisfactory degree—some to capacity—using parts in stock. On account of the activity of the radio business, the demand for small automatic screw machines has been exceptionally brisk. All the smaller sizes of these machines that were in the hands of the used-machinery dealers, have been absorbed, and one of the well-known makers of small automatics quotes from six weeks' to three months' delivery. The demand for special machinery of certain types is also good, gear tooth grinding machines particularly being in demand, one shop operating over-time to meet this demand.

In the electrical welding machine field conditions are practically normal, the demand coming mainly from the automobile industry. Shops devoted to electric welding on a jobbing basis are also well occupied. The electrical repair and motor rebuilding business keeps the shops doing this work running at full capacity, and the electrical tool business averages about 50 per cent of normal.

Gradual Return to a Normal Business

The difficulty in making comparisons is that we have no "normal" standard with which to compare. One machine tool manufacturer, therefore, took an average of the output of his plant for the last ten years, and states that the present business is 84 per cent of that average, it being about 50 per cent of the maximum business that was done during the war years. It is of interest to note that this machine tool builder is not depending on the automobile industry for his business, but caters to the general machine-building field. Some of the well-known dealers in machine tools, having defined as normal business an average trade that will enable them to maintain their organization intact, pay overhead expenses, and realize a reasonable profit, state that business is now 50 per cent of such a normal.

In the Pittsburg district good business in second-hand machinery is reported as compared with last year; but one of the dealers states that "those who believe that the second-hand business was very brisk last year should be told that at that time most dealers in used machinery lost money." The second-hand machinery business appeared good simply because the business in new machines was small. The trade in both second-hand and new machines is now more active. In the used machinery field, large types are especially in demand, but the present owners want too high prices, sometimes as high as the present reduced prices on new tools.

Dealers who handle both new and second-hand machines in the Pittsburg district state that it is still much easier to sell second-hand machines than new machinery, because many firms that never bought used machines in the past are now forced to do so by financial considerations; but these shops will most likely buy only new machines as soon as they can afford to do so. In the Cleveland district this return to new machines seems to have already taken place, one dealer reporting that of his sales 85 per cent represents new machinery, and only 15 per cent used tools, his total sales being three times the sales for an equal period last year.

Small Tools and Accessories

The tap and die business averages from 25 to 40 per cent of capacity. Some manufacturers report the reamer business to be above the pre-war level. One firm states that the business in self-opening dies is about 40 per cent normal. The volume of business done in twist drills is quite large, several of the important manufacturers in this branch running their plants about 75 per cent normal, but prices of twist drills are very low.

The makers of special tools, jigs, and fixtures average about 50 per cent of a normal business, and a few of these shops are running full and even over-time. On the other hand, a great many of them have gone out of business, thereby increasing the opportunities for those that remain. It is well known that many makers of special tools started in the business during the war years, and with the return of peace conditions there could not possibly be enough business for all. Those who had the best organizations and were best qualified to meet the requirements have survived.

The vise business may be said to be practically normal. Two of the important vise manufacturers state that the volume is greater than the pre-war business. One of the large shops making vises is running practically to capacity, while others report business considerably improved, but not yet up to normal.

In the ball and roller bearing field the activity is 100 per cent; in fact, in some instances it is above 100 per cent, the overflow work being taken care of in outside shops. This activity is due mainly to the heavy demands of the automobile industry.

Forging and Foundry Business

The drop-forging shops are fully occupied, and those engaged in making automobile forgings have difficulty in meeting the demands. There is considerable demand for forgings for railroad cars, large orders for which have been placed by the roads during recent months. One of the forging shops, specializing in steam and gas engine forgings, operates at 75 per cent capacity, and one plant making general machine forgings, at from 40 to 50 per cent capacity. Prices for forgings, which were very low a year ago, have come up to a point where it is now possible to operate without a loss. The activity in the forging shops has placed a fair demand upon steam hammers, and one of the plants building this kind of machinery operates at two-thirds capacity. Business is at present fair in the forging machinery line, and one of the plants specializing in this line is putting on men, expecting a fair business in the fall, while another plant is running full time and full force in most of its departments.

The foundry business is much better, and prices of castings have increased to a level that is said to be satisfactory by the foundry operators. The die-casting business is operating at about 75 per cent capacity. The upward trend is distinct and definite.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW AMERICAN METAL-WORKING MACHINERY

The New Tool descriptions in MACHINERY are restricted to the special field the journal covers—machine tools and accessories and other machine shop equipment. The editorial policy is to describe the machine or accessory so as to give the technical reader a definite idea of the design, construction, and function of the machine, of the mechanical principles involved, and of its application.

Heald Cylinder Grinding Machine

AMONG the important factors upon which successful automobile cylinder grinding depends are the smoothness of the table movements and the rate of table feed. To insure efficiency of table operation on the machine here illustrated, a hydraulic arrangement operated by oil is utilized to drive the main table. By means of this arrangent any table feed from zero to maximum is instantly obtainable, and reversing of the table may be effected at any desired point without shock or noise. This machine is a recent addition to the line of grinding equipment built by the Heald Machine Co., 16 New Bond St., Worcester, Mass., and is known as the No. 50. It is intended for both manufacturing and repair shops. The hydraulic arrangement incorporated in its design is also applied on an automatic piston-ring grinding machine built by this firm and described in February MACHINERY.

The main driving shaft is placed on the rear of the bed as shown in Fig. 2. It is mounted in ball bearings and is designed to be driven directly from a lineshaft at a constant speed, thus eliminating the necessity of a countershaft. The grinding head and the feeding arrangement for the eccentric are similar in design to those that have been used successfully by the builders of this machine for over seventeen years. For the benefit of those not familiar with the construction, it may be stated that the locating head is made up of two eccentrics, one within the other, which give the grinding spindle a sort of planetary adjustment for accurately feeding the wheel to the work. There are three speeds for the eccentric which are controlled by a convenient lever.

The grinding spindle is driven from the driving shaft through an idler which maintains a uniform belt tension. The spindle is hardened, ground, and runs in a taper bronze bearing at the wheel end and in a self-aligning ball bearing at the pulley end. It is equipped with interchangeable pulleys which provide different speeds for the grinding wheels, so that the operator can always obtain the correct speed for the work in hand, whether using large or small wheels. The depth of cut is obtained by a feeding mechanism on the right-hand end of the rotating head. This is operated either by means of a knob when a small adjustment is desired, or

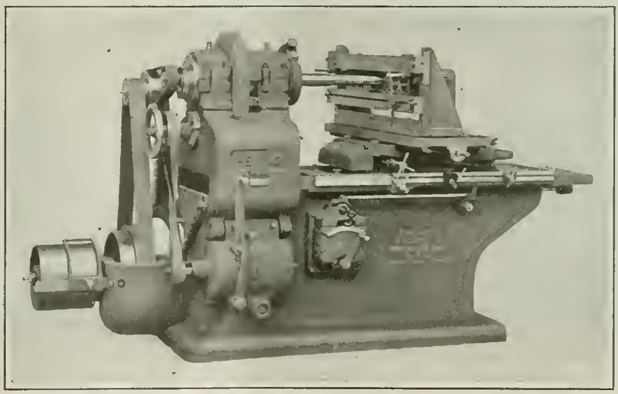


Fig. 1. Style No. 50 Cylinder Grinding Machine made by the Heald Machine Co.

through a small crank when large adjustments are to be made, as when changing the setting of the wheel to suit the grinding of different sizes of holes.

An 11–18-inch combination spindle for grinding holes 2⅜ inches in diameter and larger by 11 inches long and holes 3 inches in diameter and larger by 18 inches long, is regularly supplied, although the following sized spindles may also be furnished: 7½-inch, which grinds holes 1⅛ inches in diameter and larger by 7½ inches long; 10-inch, which grinds holes 2⅜ inches in diameter and larger by 10 inches long; 18-inch, which grinds holes 3 inches in diameter and larger by 18 inches long; 23-inch, which grinds holes 5 inches in diameter and larger by 23 inches long, and holes 3 inches in diameter by 16½ inches long; and special 15- and 18-inch spindles that are intended for use with large wheels.

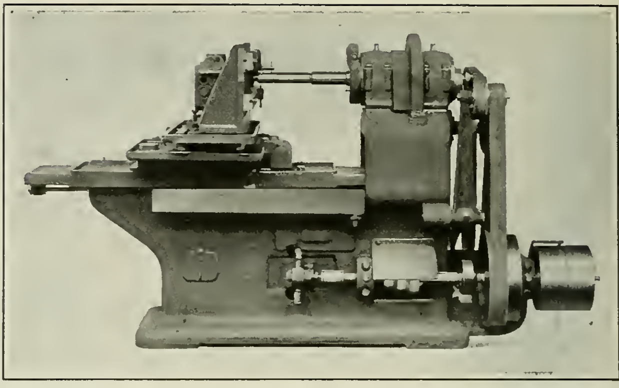

Fig. 2. Rear View of Cylinder Grinding Machine showing the Driving Arrangement

Main and Cross-slide Tables

The main table is heavy, wide, and of sufficient length to protect fully the ways on which it slides from grit or dirt. These ways are of dovetail form, and the table is gibbed to them. Oil-pockets and rolls provide adequate lubrication. The cross-slide table has an adjustment of 28 inches through a feed-screw equipped with a dial graduated to thousandths of an inch. Adjustable dogs are used to indicate long distances through which the table is moved, such as when traveling from hole to hole. Exact distances are obtained by means of the micrometer dial on the feed-screw; this can be set at zero for the first hole, and the position of the dial noted for the other holes.

A vertical adjustment of the cross-slide table up to 5/16 inch is obtainable through two inclined slides between the cross-slide table and the main table. This adjustment is made by turning a small pilot wheel connected through gears to a screw which causes the upper of the inclined slides to be moved on the lower inclined slide. In so doing the upper inclined slide causes the cross-slide table and work to be raised or lowered, depending upon the direction in which the pilot wheel is rotated.

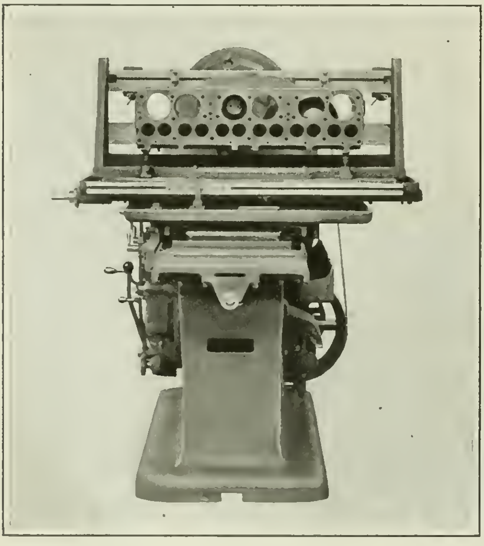

Fig. 3. End View of Heald Grinding Machine showing the Manner of setting up a Cylinder Block

As only a slight vertical adjustment is required to obtain the exact position or to take care of any vertical errors that may exist in the different bores of a cylinder casting, the 5/16-inch vertical movement of the cross-slide table is employed. To accommodate the handling of a large variety of work, a universal jig can be furnished, which locates the hole for the grinding center. When the work is of such a size that there is not a sufficient distance between the grinding center of the eccentric and the top of the cross-slide table, all slides and the cross-slide table can be removed so the operator can set up the work directly on the main table.

Universal Quick-locating Jig

A universal quick-locating jig having a capacity for all styles and sizes of cylinder blocks used with standard makes of automobiles may be furnished for the use of regrinding shops and manufacturers desiring such equipment. This jig is constructed of two bars bolted to the face of an angle casting. The bars can be so adjusted that the center of the holes to be ground will be at the correct height for the grinding wheel to enter the hole.

The standard grinding wheels for the regular 11–18-inch grinding spindle are 2¾ and 3½ inches in diameter. The speed of these grinding wheels is 4950 and 4500 surface feet per minute. A 5-horsepower motor having a speed of from 1000 to 1200 revolutions per minute is recommended for a motor-driven machine. The weight of this machine, when fully equipped with the universal jig, is about 5000 pounds.

ACKERMITE BEARING METAL

A bearing alloy consisting of copper and lead is being produced by the Ackermite Co. of America, 3643 Beaubien St., Detroit, Mich., by a patented process which is claimed to insure a uniform alloy that has no tendency toward segregation of its two components. The metal is cast solid or cored in bars 12 inches long and from ½ to 8 inches in outside diameter. These bars may be used in various ways for lining bearings; they may be remelted to allow the metal to be poured into the bearings, or they may be cut up and machined to form bearing bushings. Ackermite may be cut freely.

When used as a lining for bearings, Ackermite will wear away in time, but a shaft will not become scored while running in a bearing lined with this material. Under high temperatures resulting from lack of lubrication or especially severe service, small quantities of lead will be given off from the alloy. These particles of lead act as a lubricant which prevents bearing trouble. Ackermite may be used for lining any bearings in which babbitt is customarily employed. A somewhat similar alloy is produced by the same company for making steam-engine packing rings.

PAWLING & HARNISCHFEGER BORING, DRILLING, AND MILLING MACHINE

A high-precision horizontal boring, drilling, and milling machine which is equally adaptable to tool-room and manufacturing work has been recently developed by the Pawling & Harnischfeger Co., 3826 National Ave., Milwaukee, Wis. In a test, a surface 22 inches square is said to have been milled flat within 0.001 inch. This degree of accuracy is claimed to be possible because of the use of square-lock, narrow guides with taper gibs, and an unusually heavy construction of the spindle, saddle, and column, coupled with scraped sliding fits. All sliding members on the machine have a take-up for wear. Attention is called particularly to the centralized control, the automatic stops for the saddle and platen, and the interchangeable externally and internally driven faceplates.

From the close-up view, Fig. 2, it will be seen that all operating levers and handwheels are within easy reach of the operator and conveniently arranged for controlling the different operations. The starting, stopping, reversing and changing of feeds or speeds by hand or power are controlled by the operator without moving from his position. All levers are interlocking so that it is impossible to have two conflicting speeds or feeds in action at the same time.

The column is of heavy box construction, and grooved and tongued to the bed. The latter is also of box section and contains chutes for the quick removal of chips. The bed is cast in one piece with four walls under the column. The feeding, feed-distributing, and rapid-traverse mechanisms are contained in the bed. The platen contains T-slots and can be arranged for using cutting compound in connection with an operation. All bearings in the saddle are phospher-bronze bushed, and the main spindle sleeve bushing is also made from phospher-bronze and scraped to a light taper to furnish a means of readily taking up wear of the spindle driving sleeve. The guide on the column for the saddle is located at the front close to where the cutting pressure is applied. Adjustment for wear of the saddle is made by means of two steel tapered gibs. The saddle can be raised and lowered on the column either through a handwheel, power feed or quick traverse. A counterweight for balancing

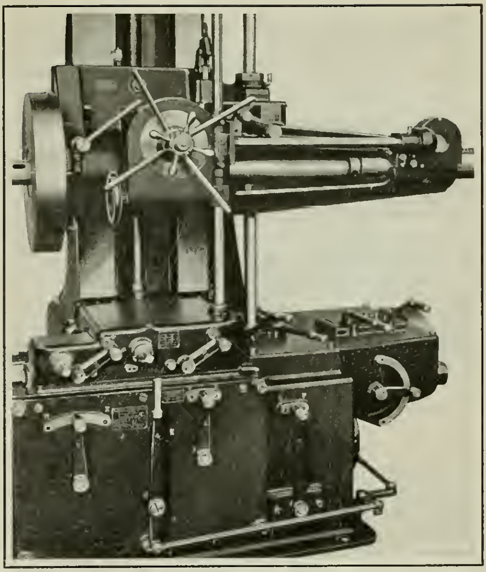

Fig. 2. Close-up View showing Centralized Control on the Pawling & Harnischfeger Boring, Drilling, and Milling Machine

the saddle members is located within the column. The spindle is a high-carbon hammered alloy steel forging, and it is ground to a sliding fit in its driving sleeve. Power for driving the spindle is applied at its front end, and power for feeding it is applied at the rear end through a rack and pinion. This construction permits the use of large bearings at the front and rear. The front end of the spindle is bored to a Morse taper and contains slots for driving milling cutters and boring-bars. The drive is delivered to the spindle either through a small faceplate by means of a wide-faced coarse-pitch gear or through a large faceplate by means of an internal gear. This large faceplate has tapped holes to provide for attaching milling cutters and facing heads. The spindle driving sleeve contains adjustable bronze taper shoes for taking up wear due to the spindle sliding in the sleeve.

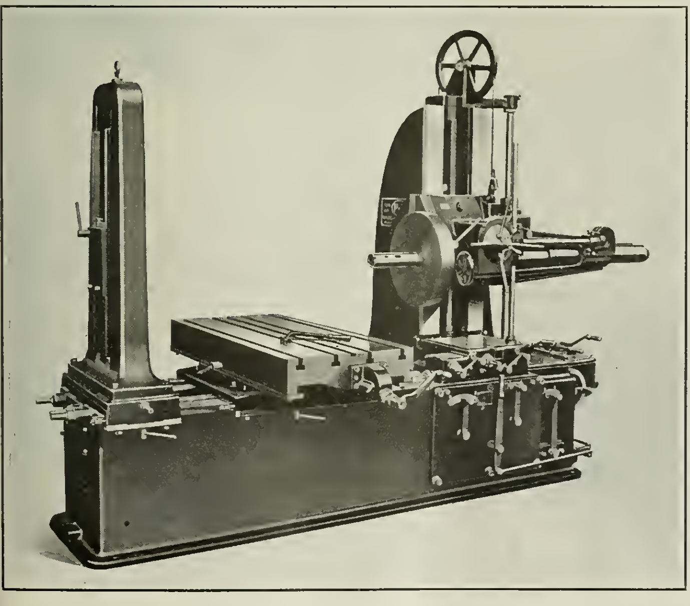

Fig. 1. No. 3T Horizontal Boring, Drilling, and Milling Machine brought out by the Pawling & Harnischfeger Co.

Sixteen speeds ranging from 14.5 to 225 revolutions per minute are obtainable with a pulley speed of 350 revolutions per minute, when the small faceplate is used. When the larger faceplate is used, the speeds obtainable with the same pulley speed, range from 8.7 to 136 revolutions per minute. Power is transmitted to the machine by a belt directly connected to a lineshaft. For a motor-driven machine a five-horsepower constant-speed motor running at a speed of from 1200 to 1400 R.P.M. is recommended.

The feeds obtainable are eight in number and range from 0.005 to 0.288 inch per revolution of the spindle for boring, and from 0.0084 to 0.44 inch per revolution of the spindle for milling, when using the small faceplate. When using the larger faceplate, feeds ranging from 0.0008 to 0.48 inch per revolution of the spindle for boring, and from 0.013 to 0.73 inch per revolution of the spindle for milling, are obtainable.

The boring-bar support can be removed from its base without disturbing any of its mechanism. Helical gearing is used between its screw and the saddle screw so as to have a minimum amount of backlash. A thread-chasing attachment can be furnished to cut threads from 2 to 16 per inch. Other attachments which may be supplied include a circular swiveling table 24 inches in diameter, graduated to minutes and having a hand or power feed; an auxiliary table 5 feet long by 5 inches wide for supporting long work; boring-bars of any diameter up to 3 inches; and a star-feed facing head for facing work up to 16 inches in diameter. The facing head can be clamped to the spindle or bolted to the faceplate. Some of the specifications of this machine are as follows: Travel of spindle, 23½ inches; maximum distance between faceplate and boring-bar support, 5 feet; maximum distance from top of platen to center of spindle, 28 inches; top surface of platen, 24 by 54 inches; cross-feed of platen with automatic trip, 36 inches; and weight, 11,300 pounds.

NEWTON CRANK PLANER

Locomotive cross-heads, shoes and wedges, die-blocks forming dies, and other parts which it is desirable to machine on a planer having a short stroke, are included in the class of work for which the heavy-duty crank shaper illustrated was designed. This machine has been brought out by the Newton Machine Tool Works, Inc., 23rd and Vine Sts., Philadelphia, Pa. The rated capacity is for work 32 inches wide by 32 inches high, and the maximum stroke is 34 inches. The base is a one-piece box casting to which the uprights, which are also of box cross-section, are bolted and doweled. The driving motor is mounted on the left-hand side of the machine, as shown in Fig. 1.

Variations in table speed are obtained through a gear-box on the right-hand side of the machine, which may be seen in Fig. 2. By means of this gear-box, 6, 8¼, 12 1/3, 17½, 23 2/3, and 35½ strokes per minute are obtainable. The gears in this box are all of the sliding type, made from hardened steel, and are fully enclosed to run in oil. The main driving gear is of the helical type, has a face width of 4½ inches, and a diameter of 37 inches. It drives the rocker arm, and gives a relatively uniform speed to the table, although the speed is slightly lower at the beginning of a cut. The compactness of the drive will be apparent by reference to Fig. 2.

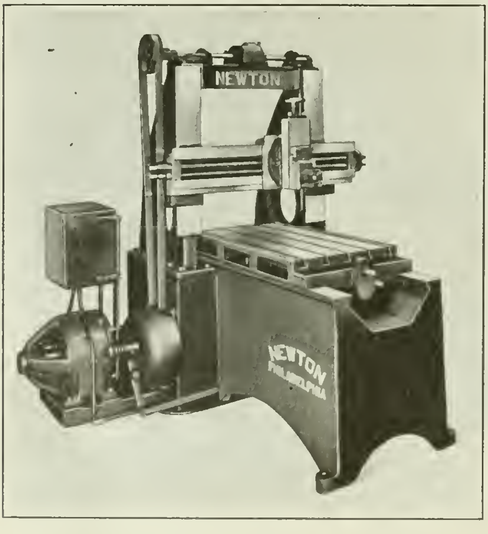

Fig. 1. Heavy-duty Crank Planer built by the Newton Machine Tool Works, Inc.

The table is of the double-plate construction, and has an adjustment of 20 inches, which can be made while the machine is in operation. After the table has been positioned, the driving element is solidly clamped by means of the square-end shaft at the front end of the table. The length of stroke is set from the operating side of the machine, an indicator showing the stroke for which the machine is arranged at any given time.

The table operation is controlled by means of a clutch and brake operated by a lever on the right-hand side of the machine (not shown in the illustration). Provision is made for locking this lever when it has been moved to the disengaged position to prevent it from re-engaging and possibly injuring the operator. The feeding mechanism is of the cycle type, being operated during the return stroke of the machine. Power is transmitted to the cross-rail through a rack and pinion to furnish the transverse, downward, and angular feeding movements. The cross-rail is raised and lowered by screws driven from the shaft extending along the top brace. In an operation, this machine has taken cuts ⅜ inch deep on steel forgings, with a feed of from 1/16 to ⅛ inch per stroke.

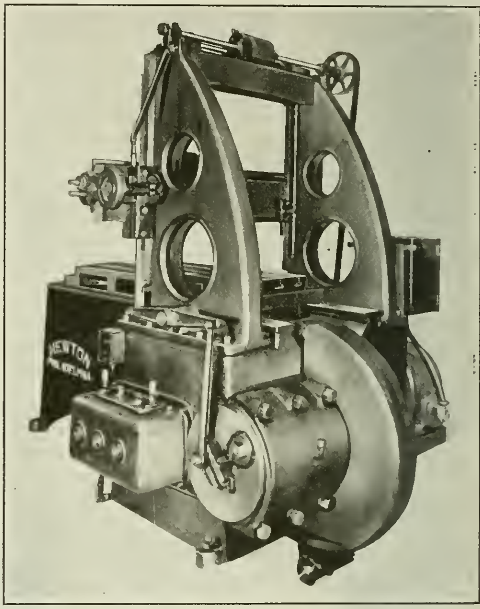

Fig. 2. View of Newton Crank Planer showing the Compact Design of the Units on the Operating Side

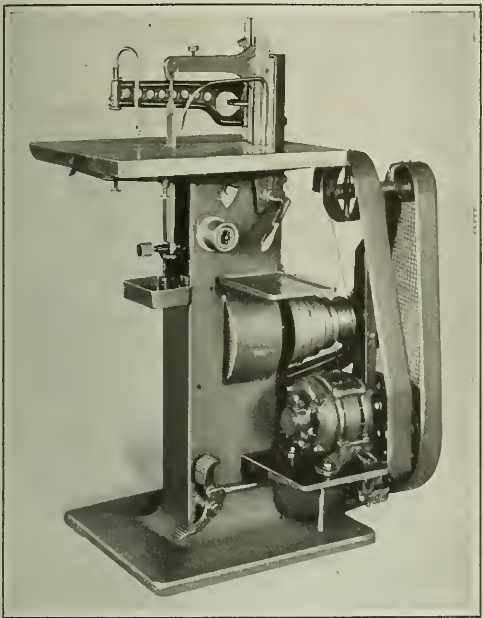
OLIVER HIGH-POWER FILING MACHINE

To permit the rapid filing of work up to 9 inches in height (although work up to 6 inches in height is recommended when the machine receives constant use), the Oliver Machinery Co., Grand Rapids, Mich., is building the filing machine here illustrated. This machine takes all sizes of standard or special files from a 3-inch long needle to a 14-inch bastard. The file is operated at four different speeds, ranging from 80 to 320 strokes per minute. The length of stroke is adjustable from ½ to 7 inches, the adjustment being effected by means of an eccentric inside the column, which is readily accessible. This eccentric is connected with the vertical slide mechanism by a telescopic connecting-rod, which permits the use of the different lengths of files. The four-step cone pulley used for driving the machine is directly connected to the eccentric shaft. All moving parts are balanced by a counterweight to insure smooth operation.

The working surface of the table measures 20 by 24 inches. The table tilts to provide for the filing of draft or clearance in parts. A clamping arm, which swings over the table and holds the work, is designed to so regulate the pressure on the work that it may be easily forced against the file. This clamping arm eliminates any danger of the work being forced upward with the file, and the possibility of injuring the fingers of the operator. The file is released 1/32 inch from the work on the up stroke by means of a patented arrangement in the head. This movement is produced by a cam on the inside of the cone pulley. It serves to lengthen the life of files and results in a uniform degree of clearance on dies and other particular work. A self-contained pump and diagonal grooves on the table carry filings from the point of contact of the files with the work.

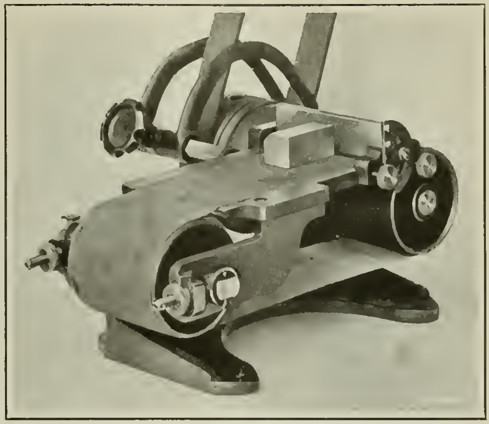


Filing Machine of a Recent Design placed on the Market by the Oliver Machinery Co.

The vertical slide has a cast-steel arm welded to its lower end on which provision is made for aligning both straight or taper files with the work. Extra attachments which may be furnished, include an overhead supporting arm for use in filing closed bottom dies or similar work, a lower supporting clamp for filing closed top dies or work of that kind, and a sawing attachment which consists of upper and lower arms for holding hacksaws. A ½-horsepower motor, operating at a speed of 1800 revolutions per minute, is mounted on the machine as shown. It is belted to a speed-reducing jack-shaft which has a yoke support that makes the machine a self-contained unit. The weight of this filing machine is about 700 pounds.

COATS ABRASIVE-BAND GRINDER

An abrasive-band grinder for straight-line finishing of all kinds of small metal parts, and for polishing fiber, vulcanized rubber, wood, and similar materials, is now being introduced to the trade by the Coats Machine Tool Co., Inc., 112 W. 40th St., New York City. Satisfactory results can be obtained in operating this grinder with unskilled help. A uniform band speed and a comparatively large grinding surface are two other advantages claimed. The work is applied to the band as the latter travels over the table. The tension on the band may be regulated to insure smooth operation, by adjusting the front band pulley, either forward or backward. This is done by turning two nuts. A graduated rest or back stop, which is detachable, may be adjusted 45 degrees either way to facilitate the grinding of angular surfaces.



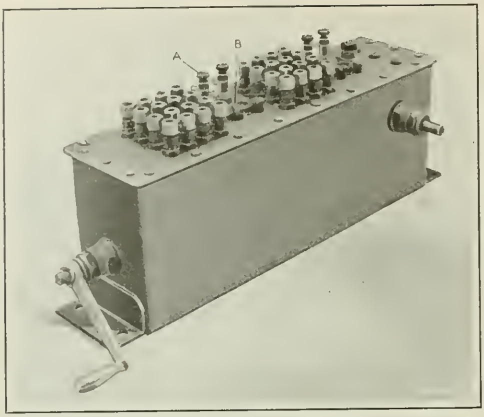
Abrasive-band Grinder recently placed on the Market by the Coats Machine Tool Co., Inc.

The loose pulley runs on a cast-iron sleeve extending from the body casting, instead of being mounted on the driving shaft, and so eliminates belt strain on the driving shaft when the machine is idle. All bearings are dustproof and are supplied with lubricators. The driving shaft runs in an oil-retaining bushing. Bands of various materials may be supplied for use on this grinder. The surface of the table measures 10 by 5½ inches, and the abrasive band is 4 inches wide by 36 inches long. The approximate weight of this grinder is 60 pounds.

MADISON-KIPP MACHINE TOOL LUBRICATOR

Adequate lubrication of the bearing surfaces on machine tools is usually a troublesome problem for designers, and so the automatic force-feed lubricator here illustrated will be of special interest to them, as well as to maintenance engineers. This lubricator is built in various styles by the Madison-Kipp Corporation, Madison, Wis., for application to practically every machine tool, from large complicated automatics to simple bench grinding machines. The device may be arranged to deliver lubricant to any number of bearing surfaces from four to one hundred without becoming bulky, the particular lubricator shown in the illustration being provided with thirty-two feeding outlets. These outlets are connected by means of tubes to the surfaces to be lubricated. The lubricator is built in a standard design, consisting of a reservoir and a cover to which are fastened pumping units for delivering lubricant to the sets of feeding outlets.

The lubricator operates on the Kipp valveless pumping principle, the main feature of which is a grooved plunger actuated by a double eccentric which causes a registration of inlet and outlet ports with the grooves of the plunger. For each stroke of the plunger, there is only one path through which oil may escape to one of the bearings fed by a pumping unit. Either four or eight outlets can be fed by each unit. The lubricator is driven by the machine it lubricates, and therefore starts and stops with it. It may be arranged with the driving shaft extending from one side of the reservoir, from one end, or from the top. The



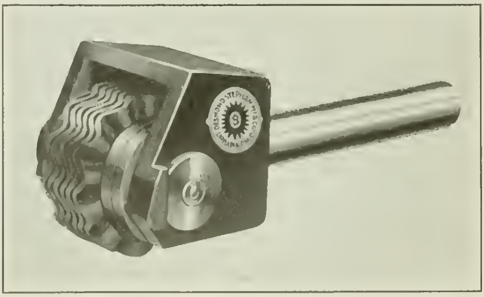
Lubricator for Machine Tools, which is manufactured by the Madison-Kipp Corporation

drive may be of a ratchet type requiring a reciprocating motion or through a pulley to which power may be transmitted from a shaft on the machine.

The amount of oil delivered to an outlet can be regulated from as little as one drop per eight revolutions of the pump driving shaft up to ten drops per eight revolutions of this shaft. This regulation is accomplished by means of a button *B* located on the cover for each set of four or eight outlets. The speed of the driving shaft may also be changed to obtain a further regulation of the amount of oil delivered. Means for observing the amount of oil being delivered by a pumping unit is provided by a test connector *A*. The reservoir is provided with an oil level indicator, filler cap, and strainer. The design of the lubricator is such that the reservoir can be made an integral part of a standard machine casting, and the cover supplied with the pumping mechanisms attached. The reservoir is sometimes built with two compartments to permit the use of two grades of oil. The crank on the lubricator furnishes a means of delivering oil when starting a machine after it has been idle for a long time.

DESMOND-STEPHAN GRINDING-WHEEL DRESSER

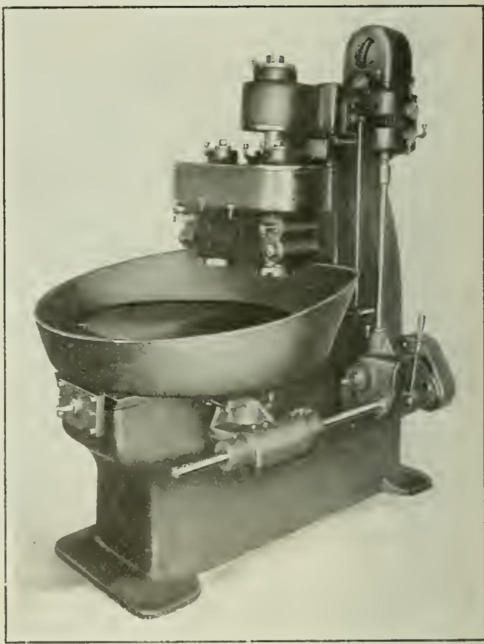
A grinding-wheel dresser in which tool-steel cutters are mounted on a bushing which revolves on a roller bearing and thus minimizes wear of the bearing surfaces, is a recent product of the Desmond-Stephan Mfg. Co., Urbana, Ohio. This dresser is designed for use either while mounted in a toolpost or on a magnetic chuck. When used with a magnetic chuck, the flat surface of the holder shown uppermost in the illustration rests on the chuck. The cutters are 2 3/4 inches in diameter, and are of a corrugated form. The rollers of the bearings on which the cutter bushing rotates revolve, in turn, on a 3/4-inch diameter pin. The bearings are dustproof, and have a simple means for oiling. It is said that in a fifteen hour test with one of these dressers, the bearings showed no indication of wear, although the cutters were reduced 3/16 inch in diameter.



Desmond-Stephan Roller-bearing Grinding-wheel Dresser

NEWTON CONTINUOUS MILLING MACHINE

Users of quantity production equipment will be interested in the new 30-inch continuous milling machine shown in the accompanying illustration. This machine has been added to the line of machine tools manufactured by the Newton Machine Tool Works, Inc., 23rd and Vine Sts., Philadelphia, Pa. The machine is shown equipped for using cutting compound, but the large pan is omitted when handling iron castings. The table of the machine has two separate and distinct types of feed, the first of which is continuous and is used for straight continuous milling. The second feed is intermittently a feed and a rapid traverse and is intended for use with limited quantities of parts or when there is considerable space between the surfaces to be machined. The rapid traverse is 10 2/3 times the rate of feed. The feeds are variable through change-gears. The table has a solid top to which jigs may be bolted and doweled. There are two bearings, one of which is of an annular type. The table overhangs the saddle only 5/8 inch, so that there is no twisting or buckling. It is rotated by a fully enclosed helical gear running in oil. The pinion that drives the table and the helical gear is rotated through worm-gearing.



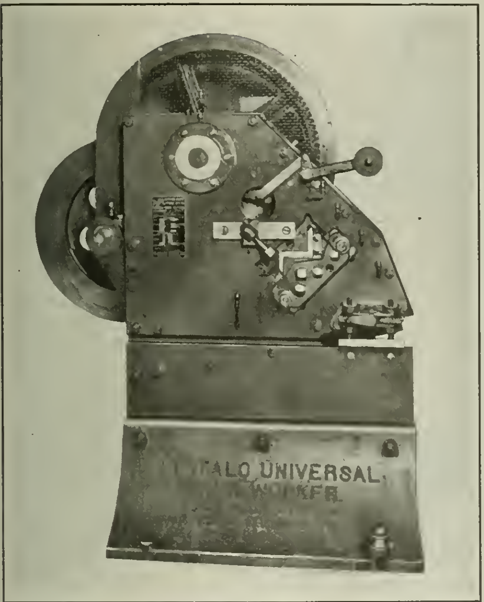
Thirty-inch Continuous Milling Machine brought out by the Newton Machine Tool Works, Inc.

A safety clutch prevents breakage of tools or machine members in the event of overloading or jamming the machine. The table saddle is adjustable on the base to permit the table to be positioned properly relative to the cutters. The two spindles have a No. 5 Morse taper hole face keyway and draw-in bolt. They are driven by hardened steel gears and supported between bearings fully enclosed and running in oil. The sleeve in which each spindle is contained has an individual end adjustment of 2 inches for setting cutters and may be clamped after such a setting has been made. The motor drives through change-gears, which provide a variation in spindle speeds.

Some of the principal dimensions of this machine are as follows: Distance from center of spindles to upright, 10 inches; distance between spindle centers, 13 inches; minimum and maximum height from top of table to lower end of spindle, 4 and 12 inches, respectively; diameter of table working surface, 30 inches; and maximum distance from center of spindle to center of table, 18 inches. The machine is driven by a 7½-horsepower motor running at 1200 R.P.M.

BUFFALO UNIVERSAL SLITTING SHEAR AND BAR CUTTER

A universal slitting shear and bar cutter, designed particularly for use in shops where punching equipment is not required, has just been placed on the market by the Buffalo Forge Co., 490 Broadway, Buffalo, N. Y. The shearing unit



New Universal Slitting Shear and Bar Cutter built by the Buffalo Forge Co.

is equipped with 10-inch knives which will cut plates ½ inch thick of any length or width, or 6- by ⅝-inch flat bars. These knives may be operated at thirty strokes per minute.

The bar-cutter unit is regularly supplied with 5-inch knives, which will cut 4- by 4- by ⅜-inch angle-iron square; 3- by 3- by ¼-inch angle-iron to a 45-degree miter, either right- or left-hand; 3- by 3- by ⅜-inch T-iron square; round bars up to 1⅝ inches in diameter, and square bars up to 1½ inches. When furnished with special knives, I-beams up to 5 inches, 9.76 pounds, and channel iron up to 5 inches, 9 pounds, may be cut, as well as other rolled sections having the same cross-sectional area. One set of blades suffices to shear both channel irons and I-beams of the same nominal size, but a different pair of knives is required for each size. This machine has an armor plate frame. About 3 horsepower is required to run this machine at full capacity. Its over-all length is 5 feet 4 inches; width, 2 feet 8 inches; height 6 feet 4 inches; and weight, 4500 pounds.

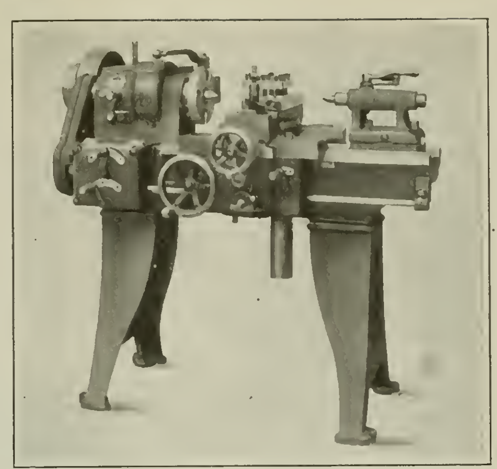


Fig. 1. Eleven-inch Rapid-production Lathe placed on the Market by the R. K. LeBlond Machine Tool Co.

LEBLOND HEAVY-DUTY RAPID-PRODUCTION LATHE

Heavier cuts, greater production, and quicker manipulation than are possible with ordinary lathes of the same size were the aims of the engineers of the R. K. LeBlond Machine Tool Co., Cincinnati, Ohio, in designing the 11-inch rapid-production lathe illustrated in Figs. 1 and 2. This machine is especially intended for small-diameter turning and facing jobs in automobile and other manufacturing plants. The headstock is of the selective speed type, and provides six speed changes through sliding gears driven from a constant-speed pulley. This pulley is driven by a multiple-disk automobile-type clutch which runs continuously in oil. The pulley revolves on a bushing, and thus relieves the driving shaft from belt pull. The six speed changes are secured through the operation of two levers.

All gears in the headstock are made of nickel steel, hardened, and have stub teeth which are rounded to facilitate their engagement. The sliding gears are mounted on short shafts having four keyways. The keys in the gears are broached from the solid. The headstock spindle runs in taper bronze bearings which are babbitt-lined and adjustable for wear, and is also provided with ball thrust

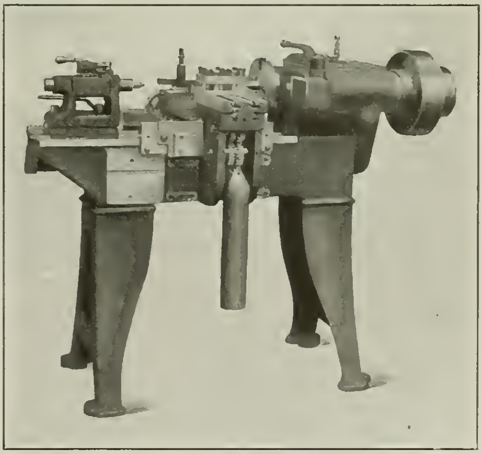

Fig. 2. Construction of Facing Attachment mounted on Rear of LeBlond Rapid-production Lathe

bearings. The spindle has a large hole extending through its entire length to permit the passing of work through it or the mounting of draw-in or expansion chucks, which may be operated either by hand or automatically. When the clutch is released from the driving pulley, a brake is automatically applied to the spindle.

The feeding mechanism is especially designed to meet the requirements of large-quantity plain turning and facing work. It consists essentially of a feed-box which provides nine feed changes for the carriage by the manipulation of two levers. The bottom lever compounds the range of feeds obtainable by means of the top lever, and this gives a quick change of feed without the necessity of gradually stepping the feed upward through a series of gear combinations until the desired feed is obtained. The feed is transmitted to the carriage by operating a lever on the apron which controls a positive clutch. The gears in the feed-box are driven directly from the spindle by means of sprockets. The sprocket chain is adjustable to vary its tension. The bearing surfaces of the carriage are scraped their entire length, and all bearings in the apron for gears and shafts are cast integral with the apron casting.

The tailstock is of an improved design, arranged to permit the quick removal and replacement of work with a single movement of the operating handle. The tailstock center may be brought into contact with the work at any desired pressure by means of a second lever, a further movement of which serves to lock the tailstock barrel rigidly and clamp the spindle. A facing attachment is furnished for work requiring facing or grooving; this attachment allows such operations to be accomplished at the same time as turning operations. The application of this facing attachment really converts the machine into a semi-automatic lathe for covering a range of smaller and lighter work than that for which the "multi-cut" lathes built by the same company are intended.

From Fig. 2 it will be seen that the facing attachment is mounted on a bracket bolted to a planed pad on the rear of the bed. The bracket is adjustable to any desired position along the bed. A roller on the attachment engages a simple cast-iron form plate bolted to and traversing with the carriage. This roller transmits the motion imparted to it by the form plate, through a rack and pinion to the facing slide, and thus feeds the latter toward the center of the lathe. The facing slide is dovetailed and gibbed to the attachment bracket. When the carriage is brought back along the bed toward its starting position, the facing attachment is also automatically returned by the counterweight. The form plate for controlling the movements of the facing attachment is readily interchangeable with one of greater or less taper to vary the movement of the slide.

Among the special equipment that may be supplied for this machine are included a draw-in attachment and collets, a turret toolpost for the carriage, an oil-pump, pan and piping, an automatic stop for the carriage, and multiple cross-stops. The principal specifications are as follows: Maximum diameter of work which can be turned, 13¾ inches; maximum length of work which can be handled, 18½ inches; range of spindle speeds, 50 to 250 revolutions per minute; range of carriage feeds, 0.008 to 0.092 inch per revolution of the spindle.

NUT CASTELLATING AND "HEXING" MACHINE

For castellating nuts and milling hexagonal ends of spark plugs, the semi-automatic machine illustrated has recently been designed by the Manufacturers' Consulting Engineers, McCarthy Bldg., Syracuse, N. Y. While the machine is primarily intended for the automobile trade, it is applicable to other operations similar to those mentioned. The machine is essentially a high-production tool. With each indexing movement of the work-holding turret, a nut, spark plug, or some other part is completed. The collets in the turret for holding the work are opened and closed automatically at the loading station, and so the only manual labor required is loading.

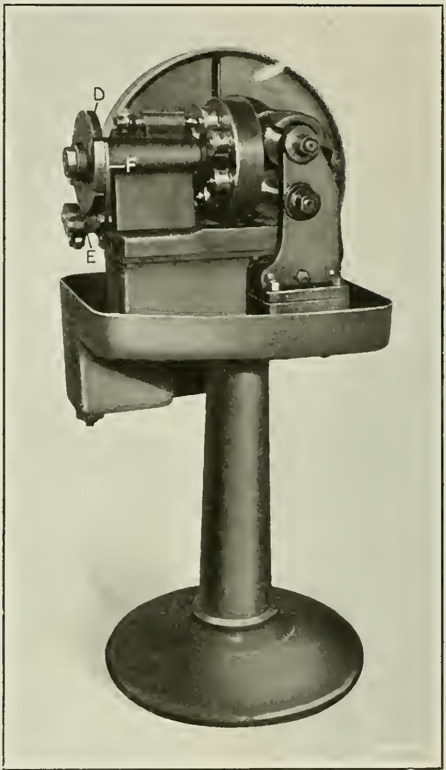

Fig. 1. Nut Castellating and "Hexing" Machine brought out by the Manufacturers' Consulting Engineers

The machine is driven through a large pulley which also serves as a flywheel. This pulley is equipped with a clutch that is operated by means of a convenient handle. From Fig. 1 it will be seen that the turret is mounted on a sliding head and has six work-holding stations. This head slides forward and backward to bring the work into and out of contact with cutters mounted on two arbors placed at right angles to the axis of the turret. The turret is indexed one position, or 60 degrees, prior to each forward movement of the head.

In Fig. 2 the two cutter-arbors *A* and *B* are provided with one and two cutters, respectively, for castellating nuts. Arbor *A* is driven directly from the main driving shaft and arbor *B* from this shaft through spur gearing. Shaft *C*, which is driven from the driving shaft through worm-gearing, extends through the machine to the indexing end. On this shaft are mounted an indexing cam and a special side cam. The front face of the side cam operates a mechanism for automatically chucking and releasing the work, and the other face imparts the feeding and returning movements to the turret head. An adjustable stop in the collets provides for placing the work properly to obtain the correct depth of cut.

In loading, the adjustable stop is pressed against an ejector that also serves as a stop, at which time the collet is automatically closed on the work. A pawl on the rear side of the index-plate *D*, Fig. 1, remains in engagement with one of the six notches in the index-plate, until the loading has been completed, when a pin on the indexing cam releases this pawl. A lobe on the cam then pivots lever

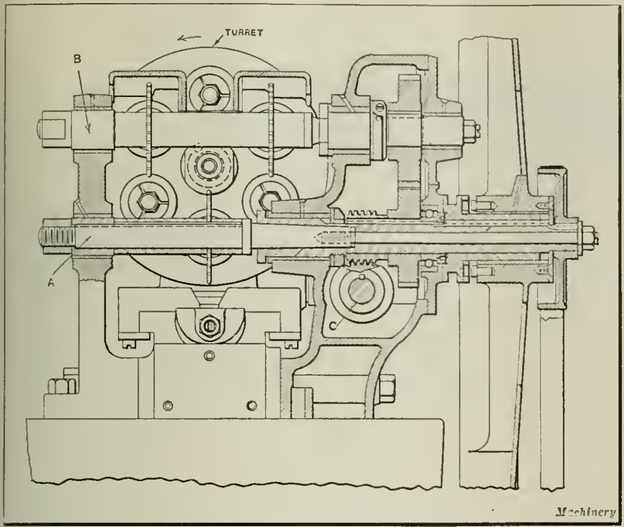

Fig. 2. Cross-section showing Method of driving the Cutter-arbors and the Camshaft

E, causing pawl *F* to engage one of six pins on the index-plate and revolve the turret through 60 degrees. As this movement is completed, the pawl at the rear again engages a notch in the index-plate and thus locks the turret.

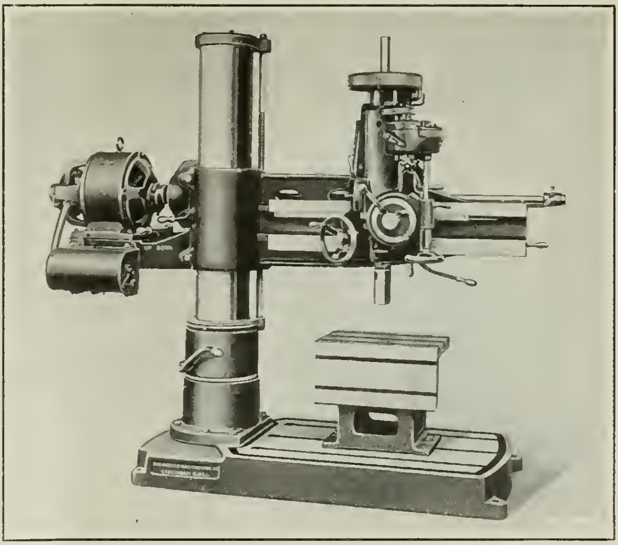
A cut is taken on three of the six pieces in the turret with each feeding movement of the turret head. Thus there is an idle station between each working station. The top one of these idle stations is used for loading. When a collet reaches the loading position, a plunger in the bearing on top of the turret head, advances into contact with the ejector, opening the collet, and at the same time allowing a spring to force the adjustable stop forward and remove the work. When this movement has ended and the operator has pushed the ejector back again in loading the collet, the plunger is withdrawn by a spring within its bearing, after which the collet is drawn in and the work chucked through the action of a series of coil springs contained in a housing on the rear of the turret.

Cutting compound is pumped to the inside of the turret spindle from a tank in the pan surrounding the machine. Passages lead from this spindle to the rear of the collets for the delivery of the compound to them. By this arrangement the compound washes out all dirt or chips, and keeps the collets clean at all times. No compound is forced to the collets when they are in either the loading or idle positions.

MORRIS RADIAL DRILLING MACHINE

In the radial drilling machine shown in the accompanying illustration, the driving motor is placed on the arm in back of the column. As a result of this design a power saving of from 20 to 25 per cent is claimed, and the number of machine parts is considerably reduced, with a consequent lessening of repairs. This machine has been recently added to the line of similar equipment built by the Morris Machine Tool Co., Cincinnati, Ohio. It is made in 4- and 4½-foot sizes. Another advantage of the design is that the motor serves to balance the arm and permits the arm to be raised and lowered on the column without straining the mechanism employed in accomplishing this. This mechanism is mounted as a unit on the back of the arm near the motor and is only in operation while the arm is being raised or lowered. The screw by means of which the up and down adjustment of the arm is obtained is always stationary.

The revolving unit of the machine is mounted on a ball thrust bearing of a capacity more than enough to carry the weight of the arm, head, motor and other details. A safety mechanism disengages the clutch which operates the arm raising and lowering mechanism when the arm reaches its extreme positions. The controller is mounted beneath the motor, within easy reach of the operator. The drill head has the same features as other radial drilling machines built by this concern, including a tapping attachment running in oil; back-gears and clutches made of nickel steel, and hardened; and helical spindle gears. All bearings are made of bronze and have an oil chamber to provide ample lubrication. The spindle speeds range from 26 to 450 revolutions per minute. A 3½-horsepower motor is required for driving the machine.

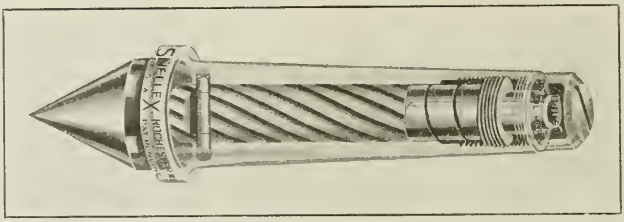


Radial Drilling Machine built by the Morris Machine Tool Co.

SNELLEX AUTOMATIC CENTERS

Difficulties met with in supporting work between the centers of lathes and grinding machines may be reduced by means of anti-friction and anti-expansion centers produced by the Snellex Mfg. Co., Rochester, N. Y. The anti-expansion center is here illustrated. It is intended for use on the headstock of a lathe to compensate for the pressure caused by the expansion of work during its machining thus eliminating the necessity of adjusting the position of the tailstock center during an operation. This center obviates the expansive force by withdrawing into its sleeve, this movement being limited by a stop-pin. An adjustable spring equalizes the cutting pressure. It is necessary to supply the center with oil only about once in six months.

The anti-friction center is intended for use on the tailstock to eliminate friction on the center and thus prevent burning of centers. It is similar in design to a center made by the same concern which was described in MACHINERY, for November, 1920, except that the balls of the race near the front are about three times larger in volume than on the original center, the size being increased to carry heavier loads. Also, the cone now has a push-fit assembly and is provided with a key instead of a lock washer. The adjusting nut is split so as to clamp itself tightly on the thread, and is made long enough to project from the sleeve for adjusting by means of a special wrench.



Anti-expansion Center placed on the Market by the Snellex Mfg. Co.

NEWTON RADIUS-LINK GRINDING MACHINE

Grinding the curved surfaces of reverse or radius links and blocks is one of the comparatively few precision operations performed in locomotive building and repair shops. To facilitate this work and to permit the grinding of other parts on which the surfaces to be ground have a radius of between 18 and 100 inches, the Newton Machine Tool Works, Inc., 23rd and Vine Sts., Philadelphia, Pa., have developed the machine shown in the accompanying illustration. The reciprocation of the table is controlled automatically by dogs. This reciprocatory motion incorporates a period of dwell to permit the operation of the vertical wheel feed and the removal of pressure during the reversal of the table. The radius at which the table reciprocates is governed by the position of a pivot bearing, which may be positioned along the radius-bar by means of a rack and pinion. A scale indicates the radius for which the machine is set at any time. The radius-bar is a tube 4 inches in diameter. The slide on which the table is mounted is fitted at both ends with a cast-iron shield to protect the surface on which the table slides. The top surface of the table contains three machined T-slots.

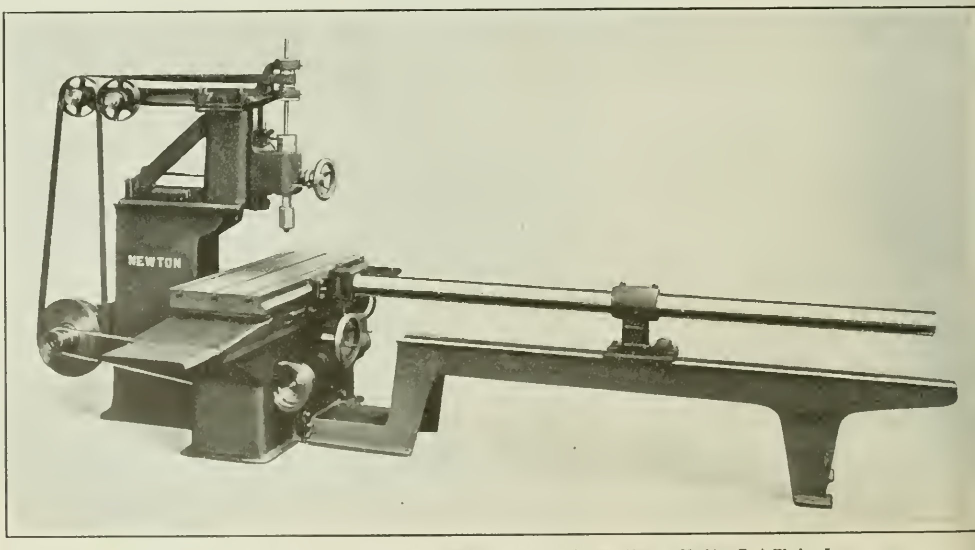
The spindle has a taper end and is provided with ball bearings. The driving pulley is carried on separate ball bearings so that there is no thrust other that that obtained by rotation. The spindle sleeve has a 3-inch adjustment in the slide. The slide is counterweighted and is adjusted by hand. It has an oscillating motion for wide-faced wheels and an intermittent feeding motion for narrow-faced wheels. This latter motion is reversible by means of a ratchet box. The spindle head is adjustable on the upright for regulating the depth of cut, and has a sufficient movement to permit the grinding of blocks as well as links.

A wheel-truing device is arranged in such a manner that the motion of the spindle slide is utilized for truing the wheel. The truing device can be readily swung out of position when not in use. The machine may be driven by a 5-horsepower motor or by a single-pulley drive.

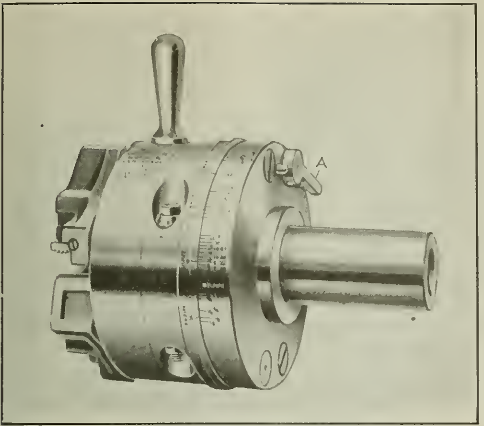
Some of the principal specifications of the machine are as follows: Spindle speed, 6000 revolutions per minute; minimum and maximum distance from center of spindle to column, 7 and 13 inches, respectively; vertical movement of spindle slide, 8⅝ inches; minimum and maximum height from spindle flange to table, 7 and 18⅝ inches, respectively; dimensions of table surface, 42 by 18 inches; minimum and maximum table stroke, 2 and 30 inches; and table speeds, 5 feet 3 inches, 7 feet 10 inches, and 10 feet 6 inches per minute.

LANDIS AUTOMATIC DIE-HEADS

An automatic screw-cutting die-head in which the chasers were supported on the face of the head was described in June, 1919, MACHINERY, at the time the tool was brought out by the Landis Machine Co., Inc., Waynesboro, Pa. This die-head was later withdrawn from the market, and after being redesigned, as shown in the accompanying illustration, it is again being introduced in five sizes, of which the 1¼-, 2- and 3-inch sizes are identical with the die-head illustrated. The ⅝- and ⅞-inch sizes are also automatic but are some-



Locomotive Reverse Link and Block Grinding Machine produced by the Newton Machine Tool Works, Inc.



Improved Automatic Die-head brought out by the Landis Machine Co.

what different, as will be mentioned later. This die-head is applicable to practically all makes of screw machines and turret lathes having a sufficient swing.

The original design was locked by the operating handle, which contained a latch having a tongue milled off center on the lower end. To adjust this head for taking either a roughing or a finishing cut, it was necessary to turn the latch to certain graduations. The new die-head is locked by engaging two hardened cylindrical pins in hardened bushings. Both roughing and finishing cuts can be taken with the three larger sizes of die-heads mentioned by moving the lock pin lever A, attached to one of the pins. The die-heads are opened automatically and closed by hand.

When cutting threads with one pass of the die-head, both lock-pins are engaged, but when cutting threads with two passes, both lock-pins are engaged for the first cut, and only that to which the lock-pin lever is attached, for the second cut. The lock-pins are machined eccentrically.

The die-head is adjustable to size by means of a screw which engages the body. The operating, adjusting, and closing rings remain in a fixed position when the head is closed, and thus, by rotating the head body within these rings, the die-head may be set to the diameters within its range. It is graduated for all sizes of right- and left-hand bolts and right-hand pipe, within its range. In setting the old-style head for left-hand threading, it was necessary to remove a screw that locked the latch pin and rotate the latter to a left-hand graduation, after which the screw was replaced and left-hand holders attached. To adjust the new die-head of the larger sizes for left-hand threading, the position of the lock-pin lever is simply reversed.

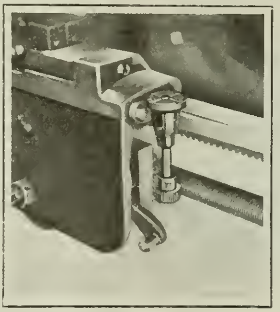
On the 5/8- and 7/8-inch die-heads the chaser and trunnions are integral. These die-heads are not provided with roughing and finishing attachments. The one set of chaser holders furnished is suitable for threading bolt and pipe within its range. Each chaser-holder and trunnion may be easily taken out of the die-head to substitute holders for special threads, by merely removing the shank and loosening one screw. The 5/8- and 7/8-inch sizes do not have the lock-pin lever. The chaser-holders and trunnions furnished with the 1 1/4, 2-, and 3-inch die-heads are separate. These sizes are regularly supplied with right-hand bolt chaser-holders for cutting U. S. standard threads but they may also be equipped for cutting S.A.E., vee, metric, Whitworth, and Briggs standard threads.

COLVEN THREAD-CHASING DIAL

Many modern lathes are equipped with a thread-chasing dial that facilitates the return of the carriage by hand to the starting point after each cut. For use on lathes not so equipped, James M. Colven, 20 Wolffe St., Yonkers, N. Y., is placing on the market the "E-Z" chasing dial illustrated. It consists essentially of a bracket attached by means of two machine screws to the rear end of the carriage on the front side. This bracket supports a vertical shaft, having a graduated dial at the upper end and a bronze worm-wheel at the lower end which meshes with the lead-screw. The worm-wheel is protected by a suitable cover. There are eight graduations on the dial, four of which are numbered and four unnumbered.

The number of teeth on the worm-wheel is a multiple of the number of threads per inch on the lead-screw, and the number of main divisions on the dial equals the number of teeth on the worm-wheel divided by the number of threads per inch on the lead-screw. Thus each main division, or the distance between two numbered or two unnumbered graduations, represents an inch of carriage travel. In re-engaging the carriage with the lead-screw, after having returned the carriage to the approximate starting point, it is only necessary to watch the dial and immediately close the apron half-nuts on the lead-screw as the proper graduation registers with a line scribed on the dial bracket.

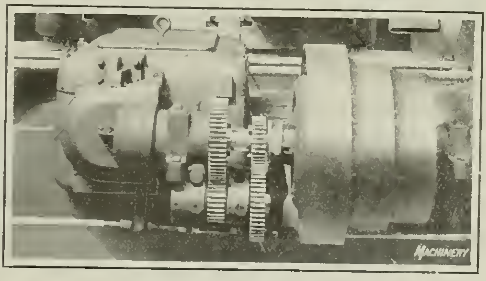
In cutting an even number of threads per inch, the nuts may be closed when any one of the dial graduations comes into alignment with the line on the bracket, but when cutting an odd number of threads per inch, only the numbered graduations are employed. In cutting 11 1/2 threads per inch, or a similar number, if the dial is set to Line 1 when beginning the first cut, the following cuts can be taken by closing the apron half-nuts when the dial is either at Line 1 or 3 until the thread is finished. The device is equally adaptable to right- and left-hand, external and internal threads. The cutting of threads close to a shoulder can be readily accomplished with this device, because the operator does not have to shift the driving belt each time the end of the thread is reached. On a lathe equipped with the dial, work may be removed for fitting into the part with which it is to be used and then easily replaced between the centers for taking additional cuts.



Thread-chasing Dial made by James M. Colven

CINCINNATI SLOW-SPEED DEVICE FOR BORING MILL

A slow-speed device has been designed by the Cincinnati Planer Co., Cincinnati, Ohio, for application to a 7-foot boring mill built by this company which was arranged for operation at a speed 30 per cent greater than standard. The machine was built for handling locomotive driving



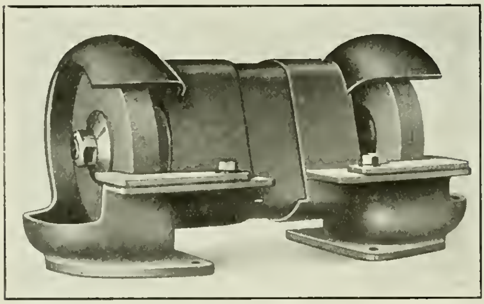
Slow-speed Device for Boring Mill which has been brought out by the Cincinnati Planer Co.

boxes and other brass parts. By means of the slow-speed device, the speed of this machine may be reduced to about 2/3 of a revolution per minute so as to also adapt the machine to the turning of tires. The accompanying illustration shows the gears of this device in mesh for driving the machine at the slow speed. The regular boring mill speeds are obtained through a direct drive when the small upper gear is slid to the left to bring its clutch teeth into mesh with those of the larger gear on the same shaft.

The friction clutch to the right of the gearing is the standard equipment for starting and stopping the boring mill. Ordinarily this clutch drives the machine through bevel gears without any of the spur gears shown. In this case the shaft is made short and the bevel gear hearing is merely used as a support. A cover which protects the gears carries a shifter for moving the sliding gear to and fro.

FORBES & MYERS TOOL GRINDER

In order to have the motor as large as possible without interfering with the grinding of long work and without destroying compactness of the design, Forbes & Myers, 178 Union St., Worcester, Mass., have provided a motor with windings only on the rear side, on the tool grinder illustrated. The motor is of the squirrel-cage induction type. As a result of this design the 6-inch wheels with which the grinder is equipped, project 1¼ inches beyond the front of the motor housing. Thus, three-quarters of the wheels may



Tool Grinder made by Forbes & Myers in Bench and Floor Types

be worn away before the periphery comes on a line with the housing. The design also permits the grinding of parts on both sides of the wheels.

The wheels that are regularly supplied are suitable for grinding tool steel; however, other grades may also be furnished. The spindle is ¾ inch in diameter at the wheels and revolves in Norma annular ball bearings which are fully enclosed. The wheel flanges are comparatively large in diameter and bear only at the outer edge. The tool rests are adjustable in two directions. The motor is of ½ horsepower, runs 3600 revolutions per minute and is fully enclosed. It can be furnished for operation on 2- or 3-phase, 60-cycle current of 110-, 220-, 440-, or 550-voltage. The bench model weighs 35 pounds, and the floor stand type, 140 pounds.

NORTON GRINDING MACHINES

Four grinding machines, one of the surface type and three of the cylindrical type, particularly adapted to the grinding of automobile parts, have been recently developed by the Norton Co., Worcester, Mass., and are presented in the accompanying illustrations. In Fig. 1, the surface grinding machine is illustrated. It is of the open-side design and has a table surface of 6 by 36 inches, on which work up to 8½ inches in width may be ground. The maximum distance from the table to the under side of the wheel is 10¼ inches.

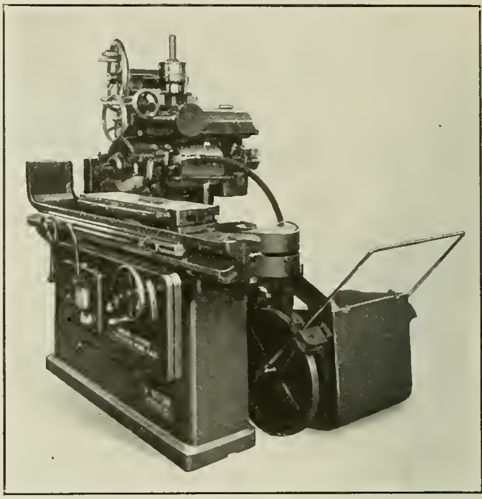


Fig. 1. Newly designed Surface Grinding Machine developed by the Norton Co.

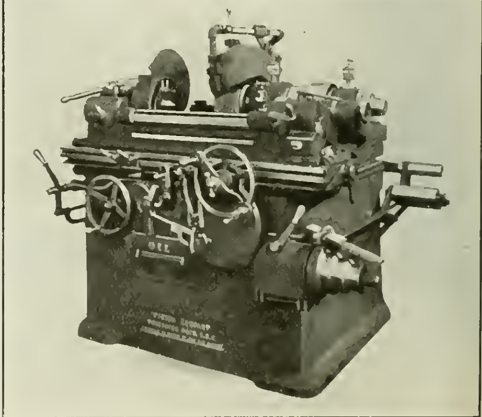
spindle bearing construction having thumb-screw adjustments and flooded lubrication. It is said that the spindle requires no attention after the thumb-screws have been adjusted, provided the spindle is rotated at its normal speed. The machine has a rapid table traverse for enabling high rates of production to be obtained. A hand table traverse is automatically engaged when the power traverse is disengaged. A 15-horsepower motor mounted on the base drives the machine. The grinding lubricant is pumped from a portable tank which can be cleaned in a few minutes without requiring interruption of the machine operation.

Some of the principal specifications of the machine are as follows: Index feed for vertical slide, 0.00025 inch; speed of table, 80½ feet per minute; dimensions of grinding wheel, 10 by 3 inches; surface speed of wheel, about 3500 feet per minute; speed of wheel-spindle, about 1340 revolutions per minute; diameter of driving shaft and spindle pulleys, 14 inches; width of the motor driving belt, 5 inches; and weight of machine, approximately, 6500 pounds.

A 10- by 18-inch plain cylindrical grinding machine is shown in Fig. 2. This machine is similar to the regular Norton 10-inch cylindrical grinding machines except that the distance between the centers has been shortened to particularly adapt the machine to grinding automobile parts.



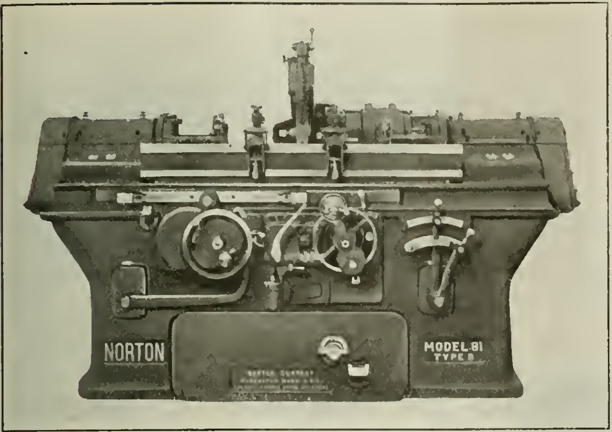


Fig. 3. Norton Model 81 Type B Crankpin Grinding Machine

The headstock, footstock, wheel-slide, and table- and wheel-feed mechanisms are the same as on the 10-inch machines.

A Model 81 Type B crankpin grinding machine is illustrated in Fig. 3. This machine has six work-speeds secured through heat-treated sliding gears which run in an oil bath. An automatic power in-feed, which is independent of the work-speed, provides a means of feeding the wheel to suit each individual crank being ground. The apron has a two-speed hand table traverse, the slower of which is used in truing. The faster speed is utilized for moving the table from one pin to another. A safety mechanism renders it impossible for the operator to injure the wheel or the work by feeding the wheel too suddenly when commencing to grind the pin. The wheel-spindle is of an improved type provided with flooded lubrication and a thumb-screw adjustment. This machine is built in four sizes weighing from about 11,400 to 11,600 pounds, this weight including the 25-horsepower motor by which each size is driven.

In Fig. 4 is illustrated a Norton 18- by 72-inch "Autopart" regrinding machine equipped with a power table traverse and arranged for a motor drive. This machine has been developed to meet the demands of regrinding shops in which there is not sufficient crankshaft work to keep busy the standard 18- by 55-inch "Autopart" regrinding machine that was described in MACHINERY for June, 1921. By adding the power table traverse, the machine is also suitable for ordinary cylindrical grinding operations. The dimensions of the wheel-slide, headstock, footstock, and other important members of this machine are the same as for these parts on the standard machine. The latter may also be equipped with a power table traverse and either a belt or motor drive.

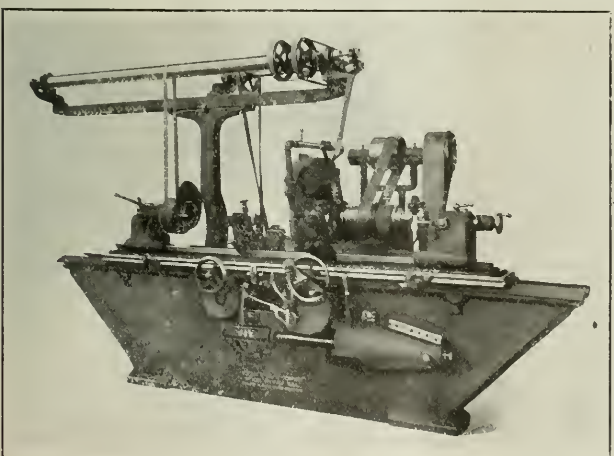

Fig. 4. "Autopart" Regrinding Machine with a Power Table Traverse

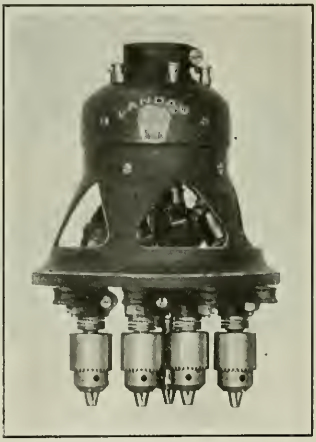
LANDAU DRILLING AND TAPPING MACHINE

A sensitive multiple-spindle drilling and tapping machine, equipped with a head having five spindles which may be instantly and individually adapted for drilling or tapping without adding or removing parts, is now being built by the Landau Machine & Drill Press Co., 45 W. 18th St., New York City. This machine, except for the head, is similar in design to a machine brought out by the same company several years ago. On the former machine the head had four spindles, and could be indexed for performing a series of operations on one hole, such as drilling, tapping, reaming and countersinking. The head on the new machine is of the design shown in the accompanying illustration. It has a capacity for drilling holes up to 1/4 inch in diameter and tapping holes up to No. 10–32.



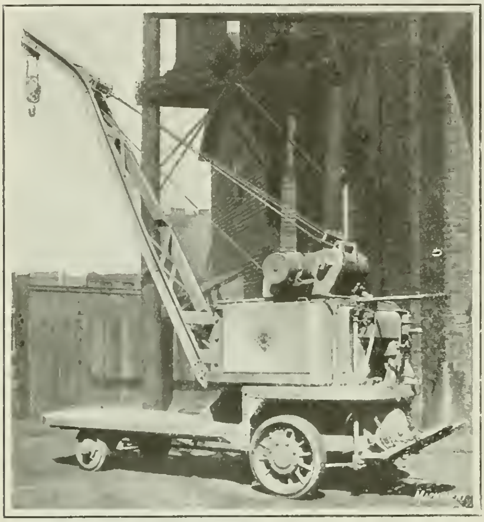
Landau Multiple-spindle Drilling and Tapping Head

The main spindle of the head is centrally located and mounted on ball bearings. The drilling and tapping spindles are adjustable relative to the center of the head by means of arms. In order to arrange a spindle for tapping when it has been employed for drilling, and vice versa, it is only necessary to loosen a set-screw. Any of the spindles can be used for tapping while the others are being used for drilling. When all the spindles are not required in an operation, those that are not to be used can be kept stationary by a simple adjustment. Each spindle may be adjusted vertically to suit short drills and taps. Upper and lower ball bearings reduce friction on the spindles. The head is fed through a rack and pinion.

Three spindle speeds of 500, 900, and 1800 revolutions per minute are obtainable by operating the belt shifter. The withdrawal speeds in tapping are 600, 1000, and 1800 R. P. M. Some of the specifications are as follows: Minimum and maximum spread of spindles, 7/8 and 4 1/2 inches, respectively; distance from center of spindle to column, 8 inches; travel of head, 3 1/2 inches; travel of table, 9 inches; weight of belt-driven machine, 300 pounds; and weight of motor-driven machine, 360 pounds.

ELWELL-PARKER CRANE TRUCK

The latest addition to the line of trucks built by the Elwell-Parker Electric Co., Cleveland, Ohio, is an electric truck having a revolving crane mounted as shown in the accompanying illustration. This equipment has a lifting capacity of 3000 pounds at a 6-foot radius and 1000 pounds at a 12-foot radius. It stacks 12 feet in height with the boom set for lifting 3000 pounds. The truck is of a heavy construction which provides sufficient stability when lifting, and absorbs the strains imposed. A single-motor double-drum hoisting unit handles a separate line to the boom and hook. The motor hoisting unit serves to counterbalance the boom and its load. The crane column is supported on a heavy pillar and revolves on ball and roller bearings. It may be swiveled through 180 degrees. The boom may be locked in any desired position and, when lowered, permits the truck to pass through a 6-foot doorway. A single battery furnishes power for the two motors of the truck. The controllers for these motors are in front of the operator. Such safety features as a crane trip switch, automatic control, worm-drive and pressure lubrication system, are incorporated in this truck.

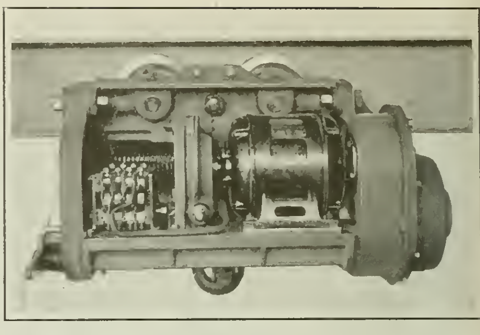


Industrial Crane Truck recently added to the Line of Equipment built by the Elwell-Parker Electric Co.

STANDARD "SHORT HEAD-ROOM" ELECTRIC HOIST

An important consideration in many hoist installations is the amount of head room required for the hoist. This factor was kept in mind by the Standard Electric Crane & Hoist Co., 1420 Chestnut St., Philadelphia, Pa. in bringing out a "Short Head-room" monorail electric hoist which is built in 1-, 2-, 3-, 4-, and 5-ton capacities. On the 3-ton size, for example, the head room is only 14 inches. In the accompanying illustration the hoist is shown with one cover removed in order to give an idea of the compact arrangement of the different units. The lifting hook is shown in its highest position.

All shafts are made of high-carbon steel, heat-treated and ground to size and have roller bearing races pressed on the ends. The bearings are of the Hyatt high-duty type. Spur gears made from forged steel are used for the drive, these gears being contained in the end housing. The pinions are made of high-carbon steel and heat-treated. The cable grooves of the hoisting drum are machine-turned and coil the rope in a single layer. The cable is connected to the exterior of the drum in a simple manner and can be easily replaced. The controller is built especially for hoisting service with all parts fireproof and completely protected from dust and moisture. The motor is of a standard make, fully enclosed and guaranteed against overheating during a half hour's continuous run. It is equipped with ball bearings.



"Short Head-room" Monorail Electric Hoist manufactured by the Standard Electric Crane & Hoist Co.

An automatic mechanical brake controls the lowering speed and another automatic brake applied on the pulley on the motor shaft and operated by a cam on the controller shaft, safely holds the load at any desired point. A device breaks the electric current and applies this holding brake when the load block reaches its upper limit of travel. Either a 2- or 4-part rope block is supplied. All gears operate in a bath of oil and automatically splash the main bearings. Bearings not oiled in this manner are lubricated by the Alemite system.

LANDAU PLAIN AND BACK-GEARED TAPPING CHUCKS

Three of a line of plain and back-geared tapping chucks recently placed on the market by the Landau Machine & Drill Press Co., 45 W. 18th St., New York City, are illustrated in Figs. 1 and 2. The back-geared chuck shown at the right in Fig. 1 is known as Model E. Its main spindle

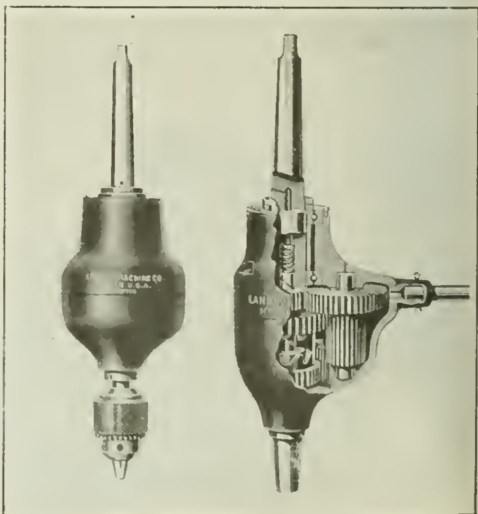


Fig. 1. Models B and E Tapping Chucks manufactured by the Landau Machine & Drill Press Co.

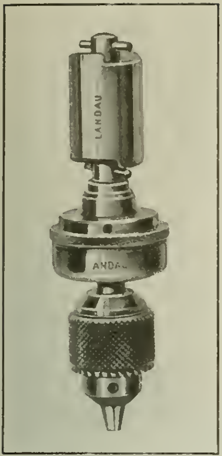

Fig. 2. Model G Tapping Chuck

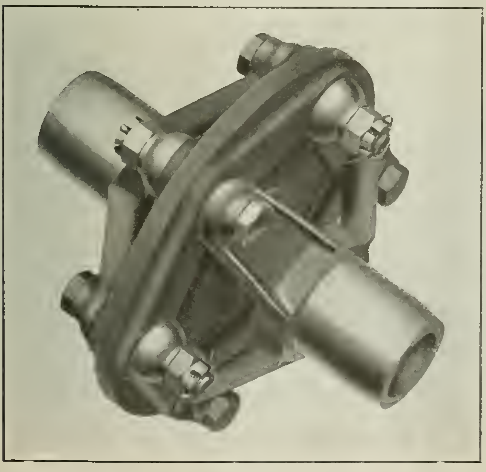
revolves on ball bearings. In using this attachment, the tapping spindle remains stationary after the tap comes into contact with the work, until the teeth of the upper driving clutch are brought into mesh with a pin on the tapping spindle. The latter is then rotated in the proper direction for tapping the hole. When this operation has been completed and the machine spindle is raised for withdrawing the tap from the hole, the tapping spindle again remains stationary until the teeth of the lower clutch of the attachment are raised into engagement with the spindle driving pin. The tap is then revolved in the proper direction for withdrawing it from the work. The Model E chuck will tap holes up to 7/16 inch, and the Model F, which is similar in design, has a capacity for tapping holes from 3/8 to 1 1/8 inches in diameter. The Model B tapping chuck shown at the left in Fig. 1 has a capacity for taps up to a 1/4 inch.

In Fig. 2 is shown a Model G plain tapping chuck which is equipped with a friction device that slips and permits the tap to stop advancing whenever a hard spot is encountered in tapping, thus preventing breakage of the tap. As illustrated, this chuck is provided with a straight shank and a sleeve which adapts it to use on a turret lathe. It is also furnished with a taper shank for use on drilling machines and engine lathes.

CLIMAX CORD DISK COUPLING

A flexible coupling intended both for use in the lineshaft installations of a shop or in the power transmitting shafts of machine tools, has been recently produced by the Climax Motor Devices Co., Chagrin Falls, Ohio. This coupling receives its flexibility from disks and cords wound in link form from bolt hole to bolt hole, thus forming a continuous reinforcing chain. Both disks and link cords are made from cotton duck. Semi-spherical projections at the bolt holes fit into the cup-shaped spider arms and cup washers. This

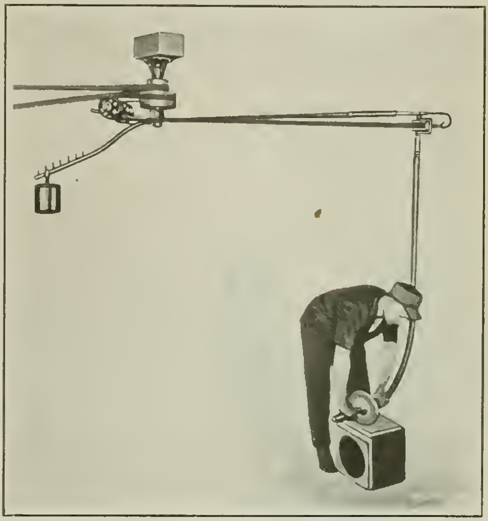


Cord Disk Coupling manufactured by the Climax Motor Devices Co.

arrangement prevents loosening of the bolts which hold the two sections of the coupling together. The flexibility compensates for all direct or angular misalignments of shafting and also absorbs shocks. This coupling is made in four sizes which have a disk diameter of 5 1/2, 6 1/2, 7 1/2, and 9 inches, respectively, and a capacity, at a speed of 100 revolutions per minute, of 1, 2, 4, and 6 horsepower, respectively.

STOW FLEXIBLE RADIAL GRINDER

A grinder intended for being driven directly from a lineshaft and having a flexible shaft at the end of an extension arm which may be swiveled to permit the use of the grinder on parts located on the floor around the equipment, is shown in the accompanying illustration. This grinder is made in five sizes by the Stow Mfg. Co., Inc., 443 State St., Binghamton, N. Y. The flexible shaft is counterbalanced by a



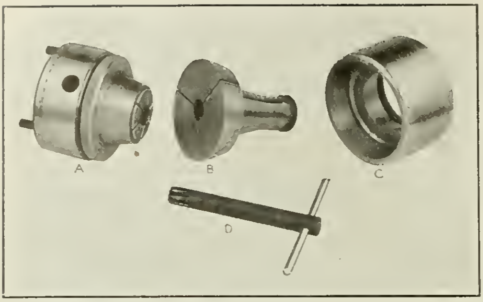
Flexible Radial Grinder made by the Stow Mfg. Co., Inc.

weight. The entire unit hangs from the ceiling, and may be driven by a motor instead of from a lineshaft as shown. In addition to being supplied for grinding operations, this equipment may be furnished with drill wire scratch brush attachments. It also serves as a convenient assembling tool when equipped with a screwdriving attachment.

HARTFORD COMBINATION COLLET AND STEP CHUCK

The different parts of a combination collet and step chuck manufactured by the Hartford Special Machinery Co., Hartford, Conn., for application to engine and turret lathes and screw, milling and grinding machines, etc., are presented in the accompanying illustration. At *A* the device is arranged as a collet chuck for attaching to an ordinary chuck faceplate. The collets are made to cover a range of work from 3/16 to 1 inch in diameter. In arranging the device as a step chuck, the knurled ring which is used to protect the thread is removed from the nose of the chuck and the collet withdrawn. The step member shown at *B* is then substituted for the collet and the closer member at *C* screwed on the threads from which the ring was removed.

The design of the collet is such that the gripping portion always seats on a straight line regardless of whether the diameter of the work varies as much as 1/32 inch from the nominal size of the collet hole. Several of the advantages

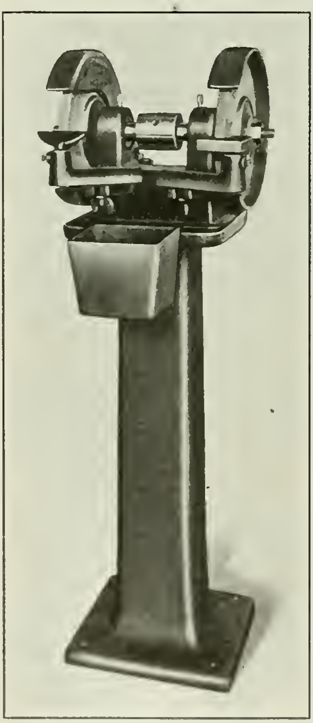


Parts of Combination Collet and Step Chuck made by the Hartford Special Machinery Co.

claimed for this chuck are that it is not necessary for the machine operator to leave his position at the front of the machine in order to tighten or loosen the chuck; a tight grip is readily obtained; and collets up to the full size of the hole through the spindle may be used.

FAFNIR BALL-BEARING TOOL GRINDER

In many machine shops the tool grinder is a source of annoyance to foremen, because those using it often neglect to stop it when they are through grinding. It was the aim of the Fafnir Bearing Co., New Britain, Conn., in developing the grinder here illustrated, to produce an equipment that could be run continuously by connecting to a lineshaft, without undue wear. The principal feature is the mounting of the grinding wheel spindle in ball bearings. The machine is driven through a pulley which is mounted on the wheel-spindle between the two ball bearings. The grinder may be supplied with a plate, instead of a pedestal for mounting on a bench, or with an offset bracket for bolting to a convenient post. It will be observed that the machine is equipped with a water pot, grinding-wheel guards, and adjustable tool-rests.

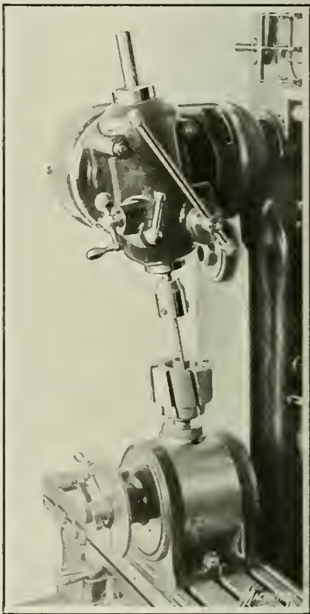


Tool Grinder built by the Fafnir Bearing Co.

ROCKFORD UNIVERSAL MILLING AND DRILLING ATTACHMENT

An attachment has recently been brought out by the Rockford Milling Machine Co., Rockford, Ill., for machines of its manufacture, which permits of milling angular surfaces or drilling holes at an angle. The illustration shows the attachment being used for reaming a taper hole in a cutter-head. The attachment is clamped to the face of the machine column, and driven by gears from the back of the main spindle through a driving sleeve substituted for the regular overhanging arm. The spindle of the attachment is driven from this sleeve through bevel gears. This driving arrangement leaves the main spindle of the machine free for use, and on many jobs it is possible to mill with a cutter in the main spindle at the same time that angular drilling or milling is being performed.

The attachment has two graduated bases located at right angles to each other, both of which can be swiveled through 360 degrees. This construction makes the spindle universal, as it can be set in any position. The spindle sleeve is graduated in inches and has an adjustment of 5 inches to increase the vertical range. Adjustments provide for compensating for wear of both upper and lower spindle sleeve bearings. The spindle is made of crucible steel, accurately ground, and runs in phospher-bronze bearings fitted with felt for retaining oil. The spindle end is bored to a No. 9 B & S taper.

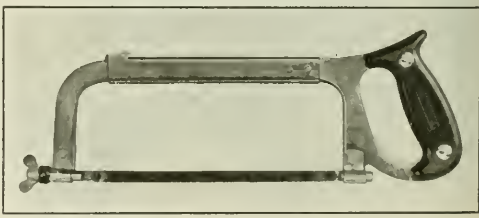


Rockford Universal Milling and Drilling Attachment

A rack and worm feed provides for boring to close limits. This feed is obtained by loosening a thumb-screw and moving the drill handle sleeve. It is in the ratio of 48 to 1, and thus permits a feed 1/48 that of the hand feed. The worm-feed handle is located at the front of the attachment within easy reach of the operator. Sixteen spindle speeds ranging from 21 to 414 revolutions per minute are obtainable and drills from 3/16 to 1¼ inches in diameter can be used. A drill chuck can be furnished.

STARRETT PISTOL GRIP HACKSAW FRAME

A number of interesting features are incorporated in the design of a new adjustable pistol-grip hacksaw frame lately brought out by the L. S. Starrett Co., Athol, Mass. On this frame a constant spring tension is maintained on the bolts



Pistol-grip Adjustable Hacksaw Frame manufactured by the L. S. Starrett Co.

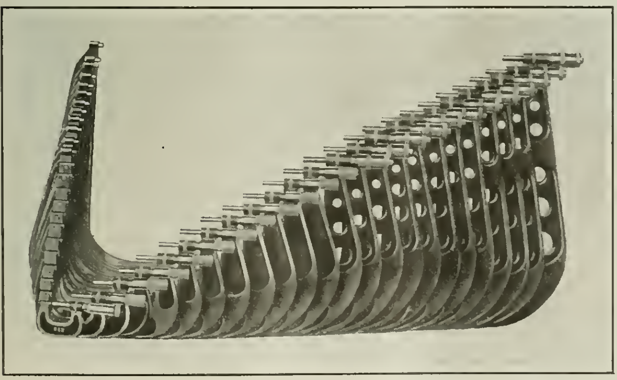
which hold the blade, and this in connection with a positive adjustment on the back which permits the use of blades from 8 to 12 inches in length, facilitates changing the blades. The pawl for adjusting to suit the length of blade is set into the frame as low as possible so as not to mar the appearance of the frame. The back is constructed of steel tubing, and all steel parts are nickel-plated. The blade may be set in any one of four positions by turning the wing-nut. It is not necessary to remove this nut entirely in order to position the blade as mentioned. The frame has a depth of 3⅜ inches from the cutting edge of the blade. The handle is made of hard rubber and checked to provide a good grip.

ATLAS "MIKRO-INDICATOR" CYLINDER AND PISTON GAGES

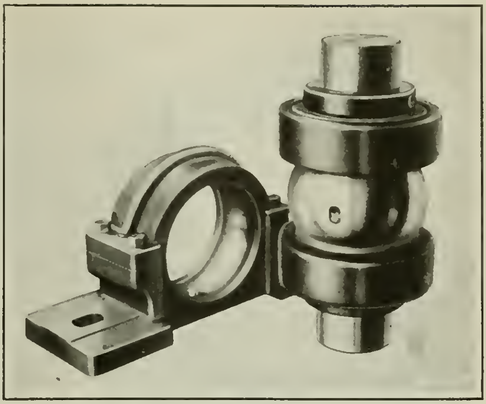
Two gages for detecting inaccuracies of automobile pistons and cylinders have been recently placed on the market by the George H. Wilkins Co., 180 N. Market St., Chicago, Ill. Both gages are equipped with an Atlas "Mikro-indicator." The cylinder gage consists of the indicator which has two contact points and a saddle having a stud upon which the indicator is supported. In testing the bore of a cylinder, the saddle is held firmly against the wall by means of a handle and is slid along the wall. Variations are shown in thousandths of an inch, and diameters from 2⅝ to 5 inches may be checked. This gage may also be used for testing turned work in a lathe, crankshaft bearings in a truing fixture, etc. The piston gage is of a bench type and is intended for rapidly checking the diameter of pistons, piston-rings, and other cylindrical parts having a diameter up to and including 6 inches. The gage has a scale for indicating the approximate diameter of the part, and the indicator shows the slight variations.

BROWN & SHARPE "REX" MICROMETERS

A new line of "Rex" micrometers made for both English and metric measure are now being announced by the Brown & Sharpe Mfg. Co., Providence, R. I. This line includes 24 sizes of micrometers for taking measurements up to 24 inches or 600 millimeters. The illustration shows the complete line in progression from the No. 59 micrometer which measures up to 1 inch, to the No. 88 micrometer which measures from 23 to 24 inches. These micrometers are regularly furnished with a ring for clamping the spindle and preserving its setting. Holes are provided in the frames of the larger sizes of micrometers to lighten them. The anvil, spindle, and other parts of this line are similar to the members furnished on the regular B & S micrometers. Means are provided to compensate for wear of measuring surfaces and the adjusting screw.



Line of Twenty-four "Rex" Micrometers made by the Brown & Sharpe Mfg. Co.



Double Ball-bearing Self-aligning Pillow-block made by the Fafnir Bearing Co.

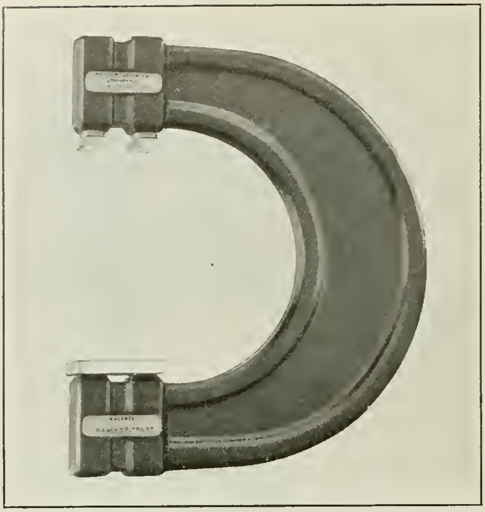
FAFNIR SELF-ALIGNING PILLOW-BLOCK

Both radial and end thrusts are taken by ball bearings in the double ball-bearing self-aligning pillow-block shown disassembled in the accompanying illustration. This pillow-block has been recently produced by the Fafnir Bearing Co., New Britain, Conn. It aligns itself to compensate for any discrepancies between the surface on which it rests and the position of the shaft that it supports. This self-alignment has no effect on the ball bearings, as they are installed in a box which aligns as a unit. Each unit has two Fafnir transmission ball bearings which have a radial ball contact and deep race grooves. The inner ring of the bearings is extra wide in order to give the bearing a firm seat on the shaft and to afford the shaft a greater support. The outer ring is mounted against a shoulder in the box. An end cap is held in place by a steel wire snapped into a groove machined in the housing. This cap contains a felt washer which prevents the escape of lubricant or the entrance of dirt.

The box is secured endwise on the shaft by collars clamped on the shaft by means of set-screws. These collars have lugs that mesh with corresponding slots cut in the wide inner rings of the ball bearings. Consequently the shaft, collars, and inner rings revolve together. The driving collars also transmit all end thrusts to the ball bearings. They abut against the inner rings, but do not come in contact with the housing or end caps. The installation of this pillow-block is an easy matter. The base can be bolted to the bed and the cap secured after the box and the shaft have been fitted in place. The shaft and box can also be removed without disturbing the base or the alignment. The shaft can be withdrawn by merely loosening the driving collars. The pillow-block may be adapted to special conditions by changing the spacing of bolt holes and the shaft center distance on the lower half of the unit.

MELDRUM-GABRIELSON ADJUSTABLE-LIMIT SNAP GAGE

A line of adjustable-limit snap gages manufactured by the Meldrum-Gabrielson Corporation, Syracuse, N. Y., was described in MACHINERY for October, 1921. Another gage now being manufactured by this concern is of the same general design but is provided with rectangular anvils which project beyond the frame a sufficient distance to permit of gaging close to shoulders. This gage is here illustrated. The position of the

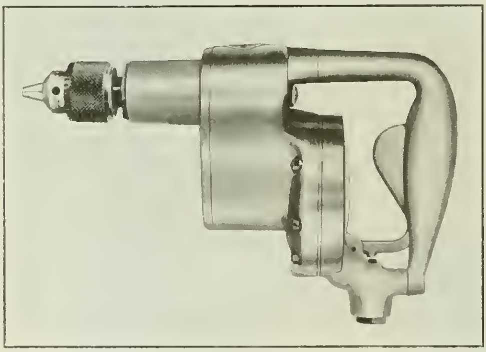


Latest Addition to Line of Adjustable-limit Snap Gages manufactured by the Meldrum-Gabrielson Corporation

two anvils at the top is adjustable, but the long anvil at the bottom has a fixed position. It is, however, possible to remove the lower anvil from the frame. The anvils project a full 1/32 inch beyond the frame.

TURBINE AIR DRILL

A portable No. 2-A "Tiny" air drill driven by a simple turbine weighing about ½ pound and having a capacity for driving ⅜-inch drills through steel and ½-inch drills through wood, has been added to the line of portable air-driven equipment manufactured by the Turbine Air Tool Co., 710 Huron Road, Cleveland, Ohio. The turbine consists of one solid piece and revolves on ball bearings. There is a clearance of 1/32 inch between the turbine and its housing. The features claimed for this drill include light weight, compactness, fewness of parts and wide range of speeds.



No. 2-A "Tiny" Air Drill manufactured by the Turbine Air Tool Co.

NEW MACHINERY AND TOOLS NOTES

Electric Hoist: Joslyn Mfg. & Supply Co., 3700 S. Morgan St., Chicago, Ill. An electric hoist having a speed-reducing mechanism consisting of three internal ring-gears, three planetary pinions and a high-speed pinion mounted on the motor shaft. This gearing gives a speed reduction of from 100:1 to 350:1 between the driving pinion and the sheave which carries the load. The hoist may be supplied with either a rope or chain lift. With the chain lift, a hook can be used on either end of the chain.

Bench Metal Saw: Triangle Metal Products Corporation, Rochester, N. Y. A bench type saw designed for the rapid cutting of small or medium-sized cold-rolled steel, drill rod, etc. It is built in two sizes, the No. 1 being intended for work from ⅛ to ½ inch in diameter and the No. 2 for work from ½ to 1 inch in diameter. The saws are 1/32 inch thick, are hollow ground to give a clean cut and are interchangeable. The machine is driven by a ⅛ horsepower motor which receives the current from a lamp socket.

Melting Furnace: Johnson Gas Appliance Co., Cedar Rapids, Iowa. A medium-size gas furnace for melting soft metals which has a removable cast-iron pot that will hold 150 pounds of metal. Three patented atmospheric Bunsen burners develop any temperature up to 2250 degrees F. and are said to consume only about 40 cubic feet of gas per hour. Two burners are sufficient for keeping the metal in the molten state. These burners have shut-off valves and pilot lights. The furnace has a direct jet regulator having an orifice that can be instantly adjusted to any pressure or to suit the quality of the gas. It sends a jet of gas up the center of the mixing tube without the use of a forced air blast or blower.

Time-study Machine: H. H. Williams, 1613 Chestnut St., Philadelphia, Pa. A time-study machine in which a strip of paper is moved at a uniform rate of speed and a pen traces a line on the moving strip. This pen is moved back and forth across the paper when the operator presses two finger keys. One of these keys is pressed at the completion of each element of a cycle in an observation. Thus the pen moves by steps across the strip. At the end of the cycle the pen is returned to its starting position by pressing on the second key. The operator can keep his eyes constantly on the workman as it is not necessary to pay close attention to the machine. The length of time between each step of the pen can be determined by means of a scale.

* * *

THE AUTOMOBILE INDUSTRY

According to a report of the Department of Commerce on industrial conditions, about 232,000 automobiles were built during the month of May in addition to 25,000 trucks. June is said to have been the largest producing month in the history of the automobile industry. Ford's June production schedule was 140,000, or a daily average of 5400 cars per working day; orders for June delivery were stated to total 195,000 cars, trucks, and tractors. The shops of the well-known automobiles were going at top speed during the month of June, and the same schedule will be continued at least until the middle of July. Equipment and parts manufacturers have a hard time keeping up with the demand. The tire industry which naturally follows the activity in the automobile industry is fully occupied, and machine shops devoted to the making of tire molds are running at 100 per cent capacity.

The manufacturers of alloy steels, the greater part of which product goes to automobile shops, are running their plants at capacity and one of the plants in this field is turning out 40 per cent greater tonnage than during the peak months in 1920. There is a growing scarcity of steel of all kinds, and deliveries are quoted far ahead. It is expected that there will be a slight reduction in automobile production in the fall, but the total production for the year is likely to be considerably greater than in 1921.

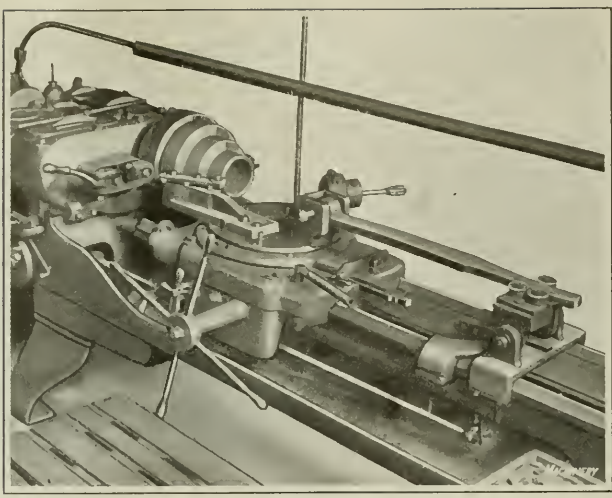
PULLEY-CROWNING ATTACHMENT

An attachment for crowning step pulleys on a Jones & Lamson flat turret lathe is used by the Valley City Machine Works, Grand Rapids, Mich., where this crowning attachment was developed. In using this device, the turret is released so that it is free to swing on its pivotal support. A bracket attached to the turret carries the cutting tools, there being one for each step on the pulley. A long bar is also attached to the turret, in line with the lathe spindle, the extended end of which has a cam surface that guides the tools in turning the crowns to the proper form. This forming bar can be tilted back by the withdrawal of two taper pins, leaving the turret clear. Inasmuch as three tools are attached to one bracket, there is, of course, a slight theoretical error in the form of the crowns, because the cam end of the bar can be correct for guiding only one crowning tool. However, the errors are insignificant, and do not affect the efficiency of the pulley.

The operation of the attachment is extremely simple. As the tools are fed across the work, in traversing the carriage longitudinally, the cam end of the bar is guided by three rollers between which it operates. This causes the turret to pivot and thus enables the tools to generate the desired crown on the pulley steps. The rollers are attached to a fixed bracket fastened to the ways of the lathe. The curvature of the cam surface is greater than that of the crown, the difference being proportionate to the radial lengths between the center of the turret and the cam-rolls, on the one hand, and the center of the turret and one tool on the other.



Turret Lathe with Cam-controlled Pulley-crowning Attachment

A device of the same general design as that illustrated is employed in this shop for taper-turning operations. The taper-turning attachment also has a cam-bar, the end of which is inclined to correspond with the taper desired on the work.

MEETING OF AUTOMOTIVE ENGINEERS

The society of Automotive Engineers held its summer convention at White Sulphur Springs, June 20 to 24. The entire first day was devoted to reports and discussion of the Standards Committee. During the following days special sessions were devoted to research, passenger cars, fuel and engines, aeronautics and motor buses. Mechanical problems were considered in papers by G. E. A. Hallett on "Methods of Developing Aircraft Engines"; by P. M. Held on "Overhead Camshaft Passenger Car Engines"; and by H. M. Crane on "A New System of Spring Suspension for Automotive Vehicles."

* * *

MEETING OF AMERICAN RAILROAD ASSOCIATION

The annual meeting of the American Railroad Association was held in Atlantic City, June 14-21. The mechanical division held its sessions during the first three days of the meeting. Reports were presented by the various committees on the cost of labor and materials; arbitration; tank cars; loading rules; train lighting and equipment; car construction; couplers and draft gears; brake shoe and brake beam equipment; train brake and signal equipment; and car wheels. Saturday, June 17, was set apart for viewing the exhibits which were unusually complete this year. There were in all about 350 exhibitors, and about 100,000 square feet was devoted to exhibit space. Among the exhibitors there were over fifty in the machine tool, small tool, and shop equipment field. The committee in charge of exhibits was complimented upon the care that had been taken in having the exhibits ready at the beginning of the convention. The scope of the exhibits was doubtless the largest of any that has been held in connection with the Railway Association conventions. In addition to machine tools and shop equipment, practically all kinds of railway equipment were exhibited, from complete locomotives and cars to the small devices used in the construction of railway rolling stock. Every square foot of space in the machinery hall on the pier was used by manufacturers of machinery and tools, and the machine tool exhibit was without question the most complete that has ever been assembled for any exhibition of comparatively short duration. A great many of the machines shown were operated during the exhibit, and many of the machine tool builders showed a number of their new developments for the first time.

AMERICAN MACHINE TOOLS AT BRUSSELS FAIR

An interesting exhibit at the Brussels Fair, consisting principally of American machine tools, is shown by the accompanying illustration. Henri Benedictus of Brussels was

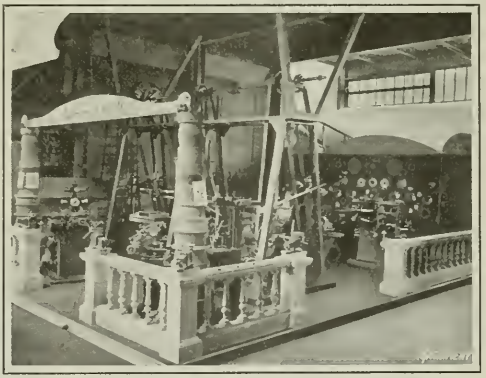

Exhibit of Henri Benedictus at Brussels Fair

the exhibitor, and the American machine tools included a Pratt & Whitney tool-room lathe and a vertical shaper; a LeBlond lathe and a milling machine; a Norton grinding machine; a Heald grinding machine; and a Stockbridge shaper. These machines were arranged for belt drive in order to provide actual demonstration. In addition, the exhibit included various forms of Norton grinding wheels, a variety of small tools from Pratt & Whitney, and files from Henry Disston & Sons, Inc.

CONSOLIDATED MACHINE TOOL CORPORATION OF AMERICA

The consolidation of five machine tool companies into a combination known as the Consolidated Machine Tool Corporation of America is announced. The new company is incorporated in Delaware, with a capitalization of $10,000,000 preferred stock, and 200,000 shares of common stock of no par value. The general offices of the company will be at 17 East 42nd St., New York City.

The merger includes the following well-known companies in the machine-tool building field: Newton Machine Tool Works, Inc., Philadelphia, Pa.; Hilles & Jones, Wilmington, Del.; Betts Machine Co., Rochester, N. Y.; Colburn Machine Tool Co., Cleveland, Ohio; and Modern Tool Co., Erie, Pa. Conferences to arrange for the consolidation have been in progress for about a year.

The officers of the new corporation have not yet been announced, but it is understood that W. H. Marshall is slated for chairman of the board of directors, and C. K. Lassiter for president. Mr. Marshall is a former president of the American Locomotive Works, and Mr. Lassiter was formerly vice-president of that company.

* * *

PERSONALS

R. P. Volkmer, formerly purchasing agent for the Tate-Jones Co., of Pittsburg, Pa., industrial furnace engineers, is now connected with the Colonial Steel Co. of Pittsburg as Cleveland representative.

William J. Merten, metallurgical engineer of the Westinghouse Electric & Mfg. Co., East Pittsburg, Pa., has been elected vice-chairman of the Pittsburg chapter of the American Society for Steel Treating.

Tobias Dantzig, formerly research engineer of S K F Industries, Inc., has opened an office at 1109 Canadian Pacific Bldg., New York City, to engage in scientific and technical consulting work. He will specialize in bearing problems and mathematical research of an engineering nature.

Ralph Templeton, for several years manager of the Whitman & Barnes Mfg. Co.'s New York office and store, assumed an important position in the company's executive offices in Akron, Ohio, on July 1. Mr. Templeton first entered the employ of the Whitman & Barnes organization in 1898, and has served it in various capacities continuously since that time. After demonstrating marked ability in the Akron office and as Detroit representative, he was appointed manager of the New York store in 1910.

John F. Schurch has been elected a vice-president of Manning, Maxwell & Moore, Inc., New York City, and has been placed in charge of western sales, with headquarters at the company's Chicago office, 27-29 N. Jefferson St. Mr. Schurch is a graduate of the University of Minnesota, and was connected for several years with the Minneapolis, St. Paul & Sault Sainte Marie Railroad. Later he became associated with the Railway Materials Co. of Chicago. In 1914 he was elected vice-president of the T. H. Symington Co., of New York.

Tillman D. Lynch, metallurgical engineer with the Westinghouse Electric & Mfg. Co., has been nominated for the presidency of the American Society for Steel Treating. Mr. Lynch is a graduate of the University of Virginia. He has been with the Westinghouse Electric & Mfg. Co. since 1899, holding various positions, among them inspector of materials, engineer of tests, section engineer in charge of manufaturing processes, and metallurgical engineer. He is the author of a number of technical papers read before various societies, and published in the technical press.

Harry M. Wey has been appointed manager of the Chicago district for the Pittsburg Testing Laboratory, with headquarters at 1560 Monadnock Block. Mr. Wey was previously connected with the Pennsylvania Railroad, holding the office of superintendent of motive power at Columbus, Ohio, and later was associated with the Illinois Central and the Atchison, Topeka & Santa Fe Railroads. From 1905 until 1909 he was in the mechanical department of the Pennsylvania Lines west of Pittsburg, after which he entered the sales department of the United States Metallic Packing Co.

J. J. Gibson, manager of the supply sales department of the Westinghouse Electric & Mfg. Co., East Pittsburg, Pa., has been made assistant to the vice-president. In his new position Mr. Gibson will have general supervision over the activities of both the supply sales department and the recently established merchandising sales department. He has been associated with the company for over twenty years. From 1900 to 1905 he was connected with the Chicago office, after which he was sent to Philadelphia. He was appointed district manager of the Philadelphia district in 1906, and in 1914 was promoted to the managership of the supply department at East Pittsburg.

Samuel T. Freas, of Henry Disston & Sons, Inc., Philadelphia, Pa., has been awarded the Edward Longstreth medal by the Franklin Institute in recognition of his invention of the interlocking tooth metal-cutting saw. This medal is awarded by the Franklin Institute on recommendation of the Committee on the Sciences and the Arts for "inventions of high order, and for particularly meritorious improvements and developments in machines and mechanical processes." Mr. Freas has been asssociated with Henry Disston & Sons, Inc., for the last twenty-one years. The saw for which he was awarded the medal was designed and developed by him in the Disston factory, and is manufactured as a standard Disston product.

Frank W. Oliver has become connected with the sales organization of the Whitman & Barnes Mfg. Co., Akron, Ohio. Beginning July 10 he will become eastern sales manager of the company, with headquarters at the New York store, 64 Reade St. Mr. Oliver has been connected with the drill and reamer industries since 1899, when he became a salesman for one of the twist drill manufacturers, and for six years he covered the United States and Canada for this concern. In 1905 he became associated with another well-known company in the same field as representative in the Chicago territory. For fifteen years he remained with this corporation, being district manager in charge of western sales for six years.

Joseph F. Keller, vice-president of the Keller Mechanical Engraving Co., of Brooklyn, N. Y., has been awarded the Edward Longstreth Medal of Merit for Invention, in consideration of substantial improvements and inventions made by him in the art of mechanical die cutting, as represented in the Keller automatic die-cutting machine of the reproducing type. The citation accompanying the medal was in part as follows: "The Institute believes credit should be given to Mr. J. F. Keller for having met a recognized need for increasing die production and reproduction over that which was possible by the old hand method and skilled operators. His efforts have resulted in quicker and better production by less skillful operators and a reduction of the costs."

W. E. Whiting is now associated with the Greenfield Tap & Die Corporation, Greenfield, Mass., representing the machine tool division of the company. He will specialize on the "Hydroil" internal grinder of this company's manufacture, which has been recently placed on the market. His headquarters will be at 2990 Concord Ave., Detroit, Mich. Mr. Whiting has been connected with the grinding industry for fourteen years. From 1909 to 1916 he was with the Heald Machine Co. of Worcester, Mass., serving as apprentice, journeyman grinder, demonstrator, and finally as superintendent of the grinding department. In 1916 he went with the Norton Co., doing laboratory and demonstration work for a short time. For the last four years he has been handling sales for the grinding wheel division of the Norton Co. in Michigan, and is therefore well known in that territory.

William H. Eager, since 1918 first vice-president of the Whitman & Barnes Mfg. Co., Akron, Ohio, has been made president of that organization to succeed A. D. Armitage, who has resigned in order to give more of his time to his duties as vice-president and general manager of the J. H. Williams Co. Mr. Eager is a graduate of the Massachusetts Institute of Technology, and for the last sixteen years he has been with the Whitman & Barnes Mfg. Co. At first he was assistant superintendent of the Chicago factory, and later became works manager. In 1908 he was elected treasurer, and in 1909 he was transferred to Akron when the executive offices were removed to that city. In 1911 he was made sales manager, and was elected first vice-president in 1918. Mr. Armitage, whom he succeeds as president, will still remain a member of the Whitman & Barnes Mfg. Co.'s board of directors.

OBITUARY

Benjamin Hill Bristol, for many years president of the Bristol Co., Waterbury, Conn., died at his home in Platts Mills, May 25. Mr. Bristol was badly injured when hit by a trolley car last July, and never fully recovered from his injuries. He was born in Naugatuck in 1837, and was in the employ of the Platts Mill Co. for forty years. In 1889 he assisted in organizing the Bristol Co., and was its president until a few years ago.

PROPOSED REDUCTION IN SECOND-CLASS POSTAGE RATES

A reduction in the second-class postage rates, which were originally imposed as war taxes but which have since been retained, is provided for in a bill which was introduced in the House of Representatives by Representative M. Clyde Kelly of Pennsylvania. This bill proposes to repeal the last two of the four increases in postal rates which have been made under the war revenue law of 1917. It is pointed out in a statement by Mr. Kelly that the publishers of periodicals are in need of this relief from discriminatory war taxation in order that they may be able to continue to serve the public effectively. The rates that would be established in accordance with Mr. Kelly's bill would still be 175 per cent higher than the pre-war rates; the present rates are 325 per cent higher than pre-war rates.

Educational periodicals, in particular, should not be taxed for revenue purposes, but should be expected merely to pay for the service rendered in carrying this class of mail matter. The fact that the higher rates are charged on the advertising pages does not lessen the injustice. Advertising is not merely merchandise, but information. Mechanical periodicals are information highways, just as essential to business prosperity as are regular highways and waterways. The advertisements in mechanical periodicals are the chronicles of every advance in industrial achievement, and without them the publication of the educational information in magazines would be impossible.

COMING EVENTS

August 28-September 2—Annual Safety Congress of the National Safety Council in Detroit, Mich. Secretary S. J. Williams, 168 N. Michigan Ave., Chicago, Ill.

September 11-16—Eighth national exposition of chemical industries in the Grand Central Palace, New York City. Managers, Charles F. Roth and Fred W. Payne, Grand Central Palace, 46th St. and Lexington Ave., New York City.

October 2-7—Annual convention and exposition of the American Society for Steel Treating in Detroit, Mich., General Motors Bldg. Secretary, W. H. Eisenman, 4600 Prospect Ave., Cleveland, Ohio.

December 7-13—National Exposition of Power and Mechanical Engineering at the Grand Central Palace, New York City. Charles F. Roth, manager, Grand Central Palace, 46th St. and Lexington Ave., New York.

NEW BOOKS AND PAMPHLETS

Thermal Stresses in Chilled Iron Car Wheels. By G. K. Burgess and R. W. Woodward. 34 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Technologic Paper No. 209 of the Bureau of Standards. Price, 5 cents.

Graphic Comparison of Screw-thread Pitches. Chart published by the Department of Commerce, Washington, D. C., as Miscellaneous Publication No. 49 of the Bureau of Standards.

The chart shows the number of threads per inch and pitch in millimeters for both inch and millimeter systems, and comprises a graphical determination of the relation between English and metric screw-thread pitches.

The A B C of Vacuum Tubes in Radio Reception. By E. H. Lewis. 132 pages, 5 by 7½ inches. Published by the Norman W. Henley Publishing Co., New York City. Price, $1.

This is an elementary book describing in simple language the theory and operation of the vacuum tube in a radio receiving circuit. It is written especially for beginners who know nothing about radio and very little about electricity, no previous technical knowledge being necessary to understand it. Starting with an explanation of elementary electrical terms and a list of symbols, the functioning of various vacuum tubes as detectors and amplifiers is explained step by step in a simple manner. The subject of speech distortion is discussed and its elimination explained. A section of questions and answers is included, which gives information for those who are contemplating the installation of receiving equipment or who are getting unsatisfactory results with their equipment.

Publicity Methods for Engineers. 207 pages, 5 by 7½ inches. Published by the American Association of Engineers, 63 E. Adams St., Chicago, Ill. Price, $1.50.

The purpose of this book is to make plain the principles of presenting to the public information about engineers, and to show how this is being accomplished. The book is based on the talks and discussions at the First National Engineering Conference on Public Information held by the American Association of Engineers in Chicago in 1921. It has been carefully edited to conserve the time of the reader and amended to form a working manual of modern public information methods used by associations, municipalities, public service corporations, and trade organizations in promoting favorable public opinion. The contents include five chapters covering the following subjects: Some Reasons for Publicity; the Right Conception of Publicity; Ways and Means that Bring Publicity; Getting News in the Newspapers, and the Publicity Man and what he Needs to Know.

The Gantt Chart. By Wallace Clark. 157 pages, 6 by 9 inches. Published by the Ronald Press Co., 20 Vesey St., New York City. Price 2.50.

In these times, when the problem of decreasing costs and increasing production is of vital importance to all executives and engineers responsible for production control, books dealing with different phases of scientific management are of particular interest. The book under review is a valuable addition to this class. It describes the principles and methods of construction of the Gantt management chart. The purpose of the chart is to enable work to be readily planned for a whole plant or an entire industry, so as to make the best use of available equipment and to get work done when it is wanted. The construction is such that information can be concentrated in a single sheet which would require a large number of sheets, if the usual type of curve sheets were used. The ways in which these charts have been applied are described, and all the types of charts thus far developed are explained. These include the machine record chart, the man record chart, the lay-out chart, the load chart, and the progress chart. The field of application of these carts is almost unlimited; besides their use in connection with manufacturing operations, they may also be used for office work, sales quotations, stores keeping, budgeting, and other activities.

Machine Shop Work. Pamphlet published by the Bureau of Education of the United States Department of the Interior, Washington, D. C. Sent free on application.

This little pamphlet contains an outline of a reading course on machine shop work, including electric and oxy-acetylene welding, prepared by the American Library Association for the Bureau of Education of the United States Department of the Interior. This pamphlet points out that mechanical drawing and mathematics are foundation studies for shop practice, and that the machinist who can read drawings, solve shop problems, and make calculations is making his services more valuable than the man who must always ask questions. The shop man should also know as thoroughly as possible, not only the operation of his own machine, but of other machines and tools used in the machine shop. It is not enough to learn by one's own experience, but one should also learn and profit by the experience of others. By studying books, it is possible to find short-cuts, avoid mistakes, and get a new understanding and a new interest in the daily task, all of which will ultimately lead to greater success. The reading course outlined contains twenty-four books, covering mechanical drawing, general shop practice, turning and boring, drilling, gear-cutting, milling, automatic screw machine work, planing and milling, die-making and die design, electric welding, and oxy-acetylene welding.

Principles of Bearings. By Louis Langhaar. 125 pages, 7 by 9 inches; 55 illustrations. Published by the Langhaar Ball Bearing Co., Aurora, Ind. Price, $2.

The purpose of this book is to present and clarify the basic principles of bearings. It resolves bearings into their elementary types, and then dissects these types, showing the few elementary principles which govern each. The five principal objects in the selection of a bearing, it is pointed out, are reliability, durability, accomplishment of a definite result, the carrying of a definite load at the lowest costs per year, per pound, or per mile—all things considered—and the attainment of the greatest carrying capacity with the least weight and bulk. The book first briefly considers plain bearings, and then gives more extended treatment to ball and roller bearings, the former being dealt with completely. In covering ball bearings, the author first deals with the evolution of ball bearings, and follows his treatment with special chapters on radial bearings, the strength of raceways, the assembling of radial bearings, thrust bearings, three- and four-point contact bearings, two-point angular contact bearings, adjustable bearings, and two-row ball bearings. Stribeck's formulas for load are dealt with, and the lubrication of ball bearings is thoroughly covered. Separate consideration is given to ball separators, material and workmanship, vibration and noise of bearings, the fitting of ball bearings on shafts and in housings, proper construction of raceways, and durability of bearings. It will be noted from this review of the contents that this book deals with all the varied problems that have been met with in ball bearing design since the early developments of the ball bearing industry. Those interested in ball bearings, as manufacturers, designers, or users will doubtless find much of interest in this book. It covers the subject both from a theoretical and a practical point of view. In referring to the fact that mathematics cannot be avoided in a proper mechanical analysis, the author states that he has made an effort to have the mathematics in this book simple and clear, bearing in mind one of the best definitions given for mathematics: "Mathematics is applied common sense."

NEW CATALOGUES AND CIRCULARS

Edison Lamp Works of General Electric Co., Harrison, N. J. Bulletin 102-A of the Lighting Data series, treating of the effect of color of walls and ceilings on resultant illumination.

Monitor Controller Co., Baltimore, Md. Circular illustrating the Monitor "Thermaload" starter, which is suitable for any size motor from the smallest up to 10 horsepower, 220 volts, two or three phase.

Paragon Machine Co., Rochester, N. Y. Circular describing Paragon blueprinting and print-drying machines. The construction of these machines is described in detail and the distinctive features are pointed out.

Watts Bros. Tool Works, Turtle Creek, Pa. Catalogue 5, illustrating and describing this company's line of square and hexagon hole drilling tools, and giving data on the saving in production costs of drilling these holes in steel, etc.

Barnhart Bros. & Spindler, Monroe and Throop Sts., Chicago, Ill. Circular descriptive of the characteristics, physical properties, and ingredients of "Tenso" die-castings. A large number of parts for which this alloy is suitable are shown.

American Spiral Pipe Works, Chicago, Ill. Circular illustrating the large variety of spiral pipe fittings produced by this concern. These fittings are furnished for all sizes of pipe from 3-inch light spiral pipe to 96-inch forge-welded pipe, 1½ inches thick.

Roeper Crane & Hoist Works, 1720 N. 10th St., Reading, Pa. Catalogue 52, containing descriptive material and tables of capacities, dimensions, and prices of Roeper I-beam trolleys, chain hoists, switches, and turntables for the overhead handling and conveying of materials.

Christiana Machine Co., Christiana, Pa. Catalogue 101, containing tabular matter covering the dimensions, horsepower transmitted, prices, etc., of the line of cast-iron spur gears, miter gears, bevel gears, spur mortise gears and pinions, worms and worm-gears, etc., made by this concern.

Thwing Instrument Co., 3339 Lexington Ave., Philadelphia, Pa. Bulletin 11, describing Thwing radiation pyrometers of the indexing and multiple-recording types, for measuring temperatures in heat-treating furnaces, coke ovens, etc., and for measuring local temperatures of dies in hardening furnaces.

Wagner Electric Mfg. Co., St. Louis, Mo., manufacturer of motors and other electric equipment, has issued a calendar for May 1922—May 1923, inclusive, designed to show three months at a glance. On each sheet is printed a brief statement of the characteristics and uses of Wagner "Pow-R-full" motors.

Condensite Co. of America, Bloomfield, N. J. Circular descriptive of the plastic molding of condensite, describing in detail how this material is molded, and the design of the molds used. The properties of condensite are explained at length. Circular containing a list of the products made by this company.

Hanson Tool & Die Co., Detroit, Mich. Catalogue containing illustrations and tables of dimensions and prices, covering the line of "West" tools made by this concern, which includes tool-

Distance lends enchantment to—lots of things but NOT to the

LUCAS MACHINE TOOL CO. NOW AND ALWAYS OF **CLEVELAND, OHIO, U.S.A.**

FOREIGN AGENTS: Alfred Herbert, Ltd., Coventry. Societe Anoyme Belge, Alfred Herbert, Brussels. Aux Forges de Vulcain, Paris. Allied Machinery Company, Turin, Barcelona, Zurich. Benson Brothers, Sydney, Melbourne. V. Lowener, Copenhagen, Christiania, Stockholm. R. S. Stokvis & Zonen, Rotterdam. Andrews & George Company, Tokyo, Japan.

holders, connecting-rod tools, end-mills and keyway cutters, counterbores and countersinks, drills, face and side milling cutters, and reamers.

E. J. Codd Co., 700 S. Caroline St., Baltimore, Md. Circular descriptive of the Wiegand chain furnace screens for oven and furnace openings, which are designed in such a way as not to interfere with the free manipulation of the tools required to handle the charge and at the same time to keep the heat in and the cold air out.

Erie Foundry Co., Erie, Pa. Bulletin 90, containing descriptive material and illustrations of Erie sheet galvanizing equipment, squaring shears, and sheet levelers. The Erie sheet galvanizing machine is designed for galvanizing flat sheets of all standard sizes and gages, and it is arranged for either belt or motor drive.

Pannier Bros. Stamp Co., 207 Sandusky St., Pittsburg, Pa. Circular illustrating the line of marking equipment made by this concern for marking trademarks, company names, or other data, on sheets, plates, and structural material. These markers are made with interchangeable rubber dies which can be quickly attached and removed.

Cooper Hewitt Electric Co., 95 River St., Hoboken, N. J., is publishing a series of pamphlets known as "Industrial Lighting Briefs" which will appear from time to time and will deal with important phases of the subject of lighting. Those who are interested in industrial lighting will be placed on the mailing list to receive copies, upon application.

Roller-Smith Co., 233 Broadway, New York City. Bulletin 560, illustrating and describing Roller-Smith enclosed circuit breakers, Types E and P. Bulletin 820, descriptive of Roller-Smith PV ammeters and voltmeters and COD indicators for automotive vehicles, farm lighting plants, battery charging outfits, small panels, and similar applications.

Crescent Pump Co., 743 Beaubien St., Detroit, Mich. Description of Crescent vacuum tools, in which application is made of vacuum for chucking flat materials and for handling and lifting flat materials of all kinds, the principle of operation being similar to that of magnetic tools. The tools shown include vacuum chucks, bench blocks, hand lifters, suction cups, oldman, and rivet hold-on.

Niagara Machine & Tool Works, 637 Northland Ave., Buffalo, N. Y. Bulletin containing instructions for the proper care of squaring shear knives. It tells what tests should be applied to the shears, and describes methods of attaching the knives, adjustment, and regrinding of the knives. The bulletin is printed on a large sized sheet, which is intended to be tacked up near the shear.

Ajax Flexible Coupling Co., Westfield, N. Y. Leaflet descriptive of Ajax flexible shaft couplings, which are made in various sizes of bores and types of driving connections for all kinds of service. The construction of the coupling is illustrated by a line engraving, and a table is included giving the dimensions and prices of the different sizes of heavy- and light-duty couplings.

MacGovern & Co., Inc., 114 Liberty St., New York City. Catalogue 51, covering the line of power machinery and contractors' equipment handled by this company, which includes turbines, motors, gas engines and oil engines, generators, converters, air compressors, centrifugal pumps, boilers, condensers, cranes and derricks, etc. The equipment listed and classified in this catalogue is ready for immediate shipment.

Hisey-Wolf Machine Co., Cincinnati, Ohio. Leaflet 3020, descriptive of Hisey electric tools, including ball bearing portable grinders and buffers, ball bearing buffing lathes, heavy-duty portable drills and reamers, toolpost grinders with combination bearings, internal and external grinders, parallel or angle-plate grinders, ball bearing bench and floor grinding machines, bench drilling stand, universal motor drills, and heavy-duty ball bearing grinders.

C. F. Pease Co., 861 N. Franklin St., Chicago, Ill. Catalogue C-61, of American-made drawing instruments, completely illustrating and describing the line manufactured by the company in its Chicago factory. It is pointed out that the manufacture of American-made drawing instruments was developed in this country as a matter of necessity during the war, and that high-grade drawing instruments of American manufacture are now available.

Sabin Machine Co., Cleveland, Ohio. Catalogue A, describing the points of construction of Sabin "one-man" trucks, which are designed for handling open-top steel and wooden barrels or boxes used in foundries, machine shops, stamping works, forge shops, and many other industries. An extension foot-pedal is used on all the trucks except Type S, thus greatly increasing the leverage and eliminating the necessity of helpers for heavy loads. Specifications are given for the various models.

Newark Gear Cutting Machine Co., 69 Prospect St., Newark, N. J. Catalogue 4, descriptive of the Newark No. 2B spur and bevel gear cutting machine, which is designed for the all-around work of machine shops, as well as for manufacturing light and medium work, such as gears used in textile work, automotive work, and special machinery. Specifications are given for this machine, and its application for cutting quill gears, gang cutting, and a number of other jobs is illustrated. Tables of tooth parts are included.

W. S. Rockwell Co., 50 Church St., New York City. Bulletin 242, on heat-treatment furnaces, illustrating a variety of methods of applying the principles of proper heating and handling to different manufacturing requirements and shop conditions. The influence of the method of heating and handling on the quality and cost of heat-treated products is pointed out, and information is given on the factors that determine the selection of the proper method. A large number of installations of heat-treating furnaces of the stationary type are shown.

David Lupton's Sons Co., Allegheny Ave. and Tulip St., Philadelphia, Pa. General catalogue 11, containing 191 pages, 8½ by 11 inches, covering the line made by this company, which includes steel sash, casement and double hung windows, rolled steel skylights, roof trusses, corrugated wire glass shelving, bookstacks, and other steel factory equipment. The attempt has been made in preparing this catalogue to make it a comprehensive and up-to-date handbook on the best practices in the use of steel sash, regardless of the make, in all kinds of buildings.

O. S. Walker Co., Inc., Worcester, Mass. Circular W2, descriptive of Walker magnetic chucks of the rectangular, swiveling, and vertical face styles, all of which are of the single coil or single magnet type of construction. Complete descriptions of the different chucks are included, as well as halftone and diagrammatic illustrations which make the construction very clear. Tables of specifications giving the dimensions, size numbers, weights, and electric current used, are included. The use of the Walker improved demagnetizing switch, which is furnished with all these magnetic chucks, is also described.

Westinghouse Electric & Mfg. Co., East Pittsburg, Pa. Circular 1579-B, treating of gears and pinions made of micarta, which is a non-metallic material that may be substituted for steel, cast iron, bronze, and other metals, when a silent drive is desired. The catalogue points out the distinctive features of micarta, and gives the physical and mechanical properties. It describes in detail the manufacture of the gears, including cutting the blanks, turning and drilling, and cutting the teeth. A number of illustrations are shown which give a fair idea of the standard construction that has been recommended and generally adopted for gear and pinion construction. Tables of horsepower ratings of micarta gears are included.

Cleveland Worm & Gear Co., Cleveland, Ohio. Bulletin 1, of Cleveland worm-gear drives, containing general information relating to Cleveland worm-gear reduction units, which are suitable for use in textile machinery, turbines, mining machinery, hoisting and conveying devices, automobiles, elevators, rolling mills, and other industrial drives. Lubrication bulletin for Cleveland worm-gear drives, giving instruction for installation, lubrication, and maintenance. Circular containing suggestions relating to the installation of Cleveland worm-drives. The information given makes it possible to obtain the most economical installation for the particular class of work to be done, the selection of a proper sized unit depending upon the load characteristics and motive power conditions. Circular entitled "The Banks are Demanding Economy," showing a blueprint that gives the horsepower and standard dimensions for Cleveland worm-drives for lineshafts.

TRADE NOTES

Wagner Electric Mfg. Co., St. Louis, Mo., has removed its Salt Lake City office to 313 Dooly Bldg.

Vandyck Churchill Co. has removed its office from the Singer Building to 52 Vesey St., New York City.

Buell, Scheib, Mueller, Inc., is a new concern of consulting and combustion engineers which is located at the Columbia Bank Bldg., Pittsburg, Pa. The company will specialize on fuel economy and conservation, and furnace design.

Perdieu Tool Mfg. Co., Milwaukee, Wis., has taken over the business and factory of the Meigs-Powell Co. and will continue the manufacture of calipers, dividers, and other machinists' tools. R. A. Perdieu is president and J. B. Matthews, secretary of the concern.

Diamant Tool & Mfg. Co., Inc., 95 Runyon St., Newark, N. J., has appointed the Cleveland Duplex Machinery Co., Inc., 1224 W. 6th St., Cleveland, Ohio, as exclusive representative for the sale of Diamant standard punch and die sets, in the territory covered by the northeastern section of Ohio.

Fred C. Dickow Machinery Co., for the last fifteen years dealer in new and used machinery and tools, and manufacturer of the Dickow 10-inch universal index-centers, has moved the main office and salesroom of the company from 3504 W. Lake St. to 2105 W. Lake St., Chicago, Ill. The new telephone number is West 1352 J.

American Stamping Co., 5400 Windsor Ave., N. E., Cleveland, Ohio, is a new concern which has been formed to specialize in all kinds of stampings. The general manager is F. W. Vilmar, and the president and works manager is W. E. Gemmill, both of whom were associated for many years with the Parish & Bingham Corporation of Cleveland.

V & O Press Co., Brooklyn, N. Y., has recently purchased additional machine shop equipment and is planning to erect an up-to-date factory on a 7½-acre tract of land which the company owns on Cooper Ave. and Long Island Railroad, Glendale. The present factory on Dry Harbor Road has become inadequate because of the increasing demand for V & O power presses and sheet metal working machinery.

United Alloy Steel Corporation, Canton, Ohio, announces the purchase of the plant of the Canton Sheet Steel Co., which was necessitated by the rapidly increasing volume of its business. The alloy plant has been running at capacity for some time, and as soon as possible the new division will be placed in full operation. The company's iron and steel products are marketed under the trade names of "Toncan" and "U-Loy."

I. B. Williams & Sons, Dover, N. H., manufacturers of leather belting, have announced the establishment of a new department of their business for the manufacture of mill strapping of all kinds. They have equipped the department with special machinery for the manufacture of every type of strapping or leather pieces of special shapes required by manufacturers in any line. T. L. Chapman will have charge of the new department.

Air Reduction Sales Co., 342 Madison Ave., New York City, at a recent meeting of the board of directors elected the following officers: First vice-president, A. R. Ludlow, formerly vice-president in charge of sales; vice-president and secretary, M. W. Randall, formerly secretary; vice-president and operating manager, Herman Van Fleet, formerly chief engineer; vice-president in charge of research and development, Dr. F. J. Metzger.

Cleveland Tractor Co., Cleveland, Ohio, manufacturer of the "Cletrac" tank-type tractor for farm and industrial uses, is to be reorganized as the Allyne-Zeder Motors Co., to manufacture and market a new six-cylinder automobile which is being designed by F. M. Zeder, formerly chief engineer of the Willys Corporation and the Studebaker Corporation. A new corporation subsidiary to the Allyne-Zeder Motors Co. will be organized under the name of the Cleveland Tractor Co., which will continue to market "Cletrac" tractors through the present distribution and dealers.

Kent-Owens Machine Co., Toledo, Ohio, has taken over the Diamond Alloy Tool Co., of St. Louis, Mo., and will in the future manufacture "Diamond Alloy," a cutting metal which is cast accurately to form in permanent molds, and is suitable for tool bits, milling cutters, cut-off blades, slitting saws, counterbores, keyway cutters, inserted blades for milling cutters, reamers, and boring tools. The metal has high wear-resisting qualities; it is tough and hard and yet not brittle. The sales of "Diamond Alloy" will be handled by P. H. Briggs, 1235 W. 9th St., Cleveland, Ohio.

Firth-Sterling Steel Co., McKeesport, Pa., has opened a branch office in Los Angeles, Cal., at 836 E. 3rd St., which will be under the charge of E. S. Jackman & Co. of Chicago, who look after all the business of this company west of Pittsburg. William E. Nelson who has been selling Firth-Sterling steels for twenty years, will have direct charge of the work. The Los Angeles office will carry in stock "Blue Chip" high-speed bits for tool-holders in all standard sizes and both square and beveled styles. Orders for tool and die steel in bars will be filled from the Chicago warehouse or from McKeesport as in the past.

Pittsburg Testing Laboratory has opened a sales office and complete inspection bureau at 1864 Railway Exchange Bldg., St. Louis, Mo. Colonel N. C. Hoyles will be district manager. Colonel Hoyles has been associated with the company for a number of years, having entered the service as inspector at the Birmingham office in 1908. In 1912 he was promoted to the position of manager in the Birmingham office, and in 1914 was transferred to the Vancouver office. At the outbreak of the war he entered the service of the Canadian Army but returned to the Pittsburg Testing Laboratory after the war was over, and has been assistant sales manager at New York and manager at Cincinnati.

Gardner Tap & Die Co., Cleveland, Ohio, has recently been incorporated for the purpose of taking over the business of the Gardner-Bryan Co. of Cleveland, manufacturer of taps, dies, and screw plates. F. W. Wood, president of the Wood & Spencer Co. and of the Cleveland Castings Pattern Co., is president of the new company; J. M. Gardner and R. H. Smart of the former Gardner-Bryan Co. are vice-president and sales manager, and treasurer, respectively, and D. G. Miller, secretary of the Wood & Spencer Co. and of the Cleveland Castings Pattern Co., is secretary. The board of directors comprises the officers mentioned and A. K. Spencer, vice-president of the Wood & Spencer Co. and the Cleveland Castings Pattern Co., F. H. Wood of Watertown, Mass., and F. E. Gardner of Beloit, Wis.

VOLUME 28 MACHINERY NUMBER 12

AUGUST, 1922

THE INDUSTRIAL PRESS, 140-148 LAFAYETTE ST., NEW YORK CITY

CONTENTS OF THIS NUMBER

CIRCULATION FOR JULY, 1922, 19,000 COPIES

Member Audit Bureau of Circulations

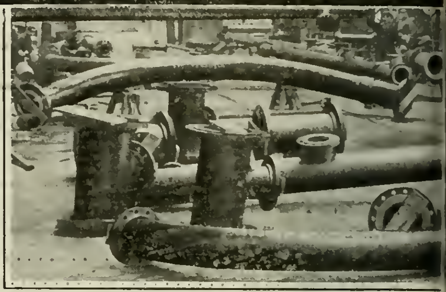
Published monthly. Yearly subscription in United States and territories, Philippines, Porto Rico, Canal Zone, Cuba, Mexico and Shanghai, $3; Canada, $4; foreign countries, $6; single copies 35 cents, postage extra. The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made payable to THE INDUSTRIAL PRESS.

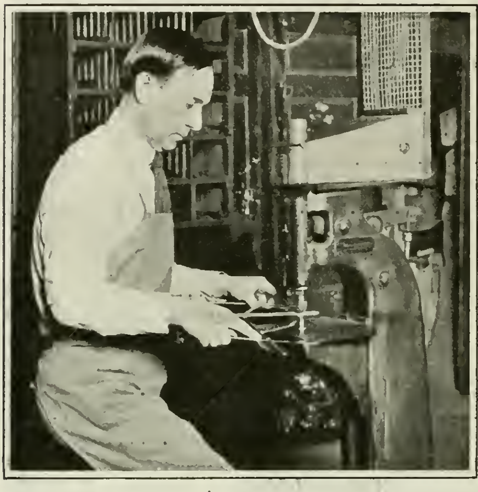
September MACHINERY will be of more than ordinary interest. It covers a wide range of unusual subjects—Diamond Tools, Rivet Spinning, Bending Large Pipe, Metal Polishing, Molding Radio Insulators, Grinding Small Tools, Wire Forming, Cutting Bevel Gears, etc.

 Entered as second-class mail matter, September, 1894, at the Post Office, in New York, N. Y., under the Act of March 3, 1879. Printed in U. S. A. It is understood that all contributed articles are submitted exclusively to MACHINERY; when accepted and published, payment is made at our regular space rates.

FOREIGN MACHINERY MERCHANTS PAGES, 246-247 PRODUCT INDEX, 248-272 ADVERTISERS INDEX, 275-276

What September

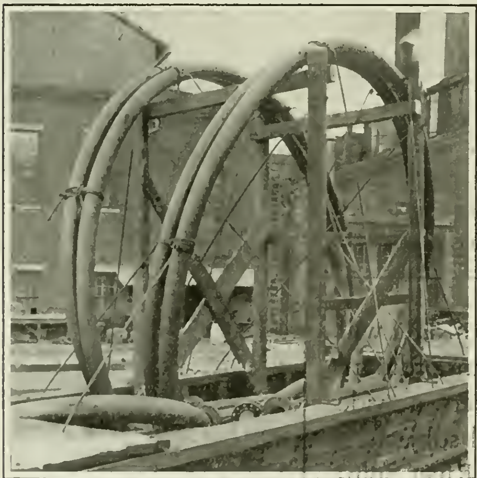




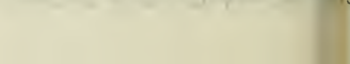
The September number of MACHINERY will be of more than ordinary interest because of the unusual subjects covered. The leading article "Bending Large Pipe" describes in detail the general practice for handling this work. Pipe up to 4 inches can be bent cold, by using machines designed for the purpose, but larger sizes must be heated. The heating process and the unusual methods employed to secure the desired shapes are extremely interesting and a great deal of skill is required to bend large pipe without flattening or buckling on the inside of the bend.

Another article—"Rivet Spinning"—deals with the use of rivet spinning machines for heading or "setting down" pins, studs and bushings as well as rivets.

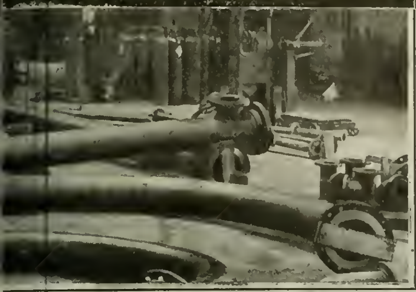
September also marks the beginning of a series on the "Principle of Metal Polishing"—covering the subject of polishing thoroughly and completely. One of the prominent manufacturers in the polishing line has written a great part of the matter and the articles will cover the general points concerning metal polishing, polishing

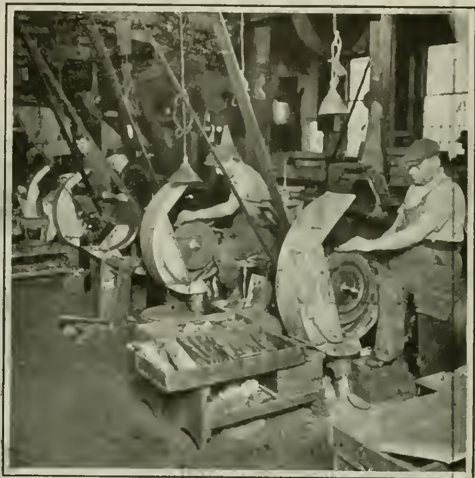


Latest Mechanical Developments



MACHINERY Offers





wheels and abrasives, polishing methods and equipment, the making of polishing wheels and special wheel shapes, together with a number of examples of polishing practice in different metal-working industries. Another instance where MACHINERY takes up a subject and deals with it completely in all its phases in a series of articles.

"Molding Radio Insulators" is another chapter in the series on making radio instruments, and includes a complete review of the dies and methods used in this work.

"Diamond Tools as Cost Reducers" indicates how diamonds may be used for cutting various materials, with special emphasis on the economies introduced by the application of diamonds as cutting tools.

"Grinding in the Small Tool Industry" continues the grinding series. The last installment of "Cutting Bevel Gears" and the second and last installment of "Wire Forming" appear in September, and the designer and draftsman will be especially interested in the article "Following up Alterations in Design."

SPECIAL FEATURES

BETTS SLOTTERS

Frame castings have the strongest section at the point of greatest stress.

The *rated* stroke and the *working* stroke are the same —the feed does not take up any part of rated stroke.

Feed screws are always in tension.

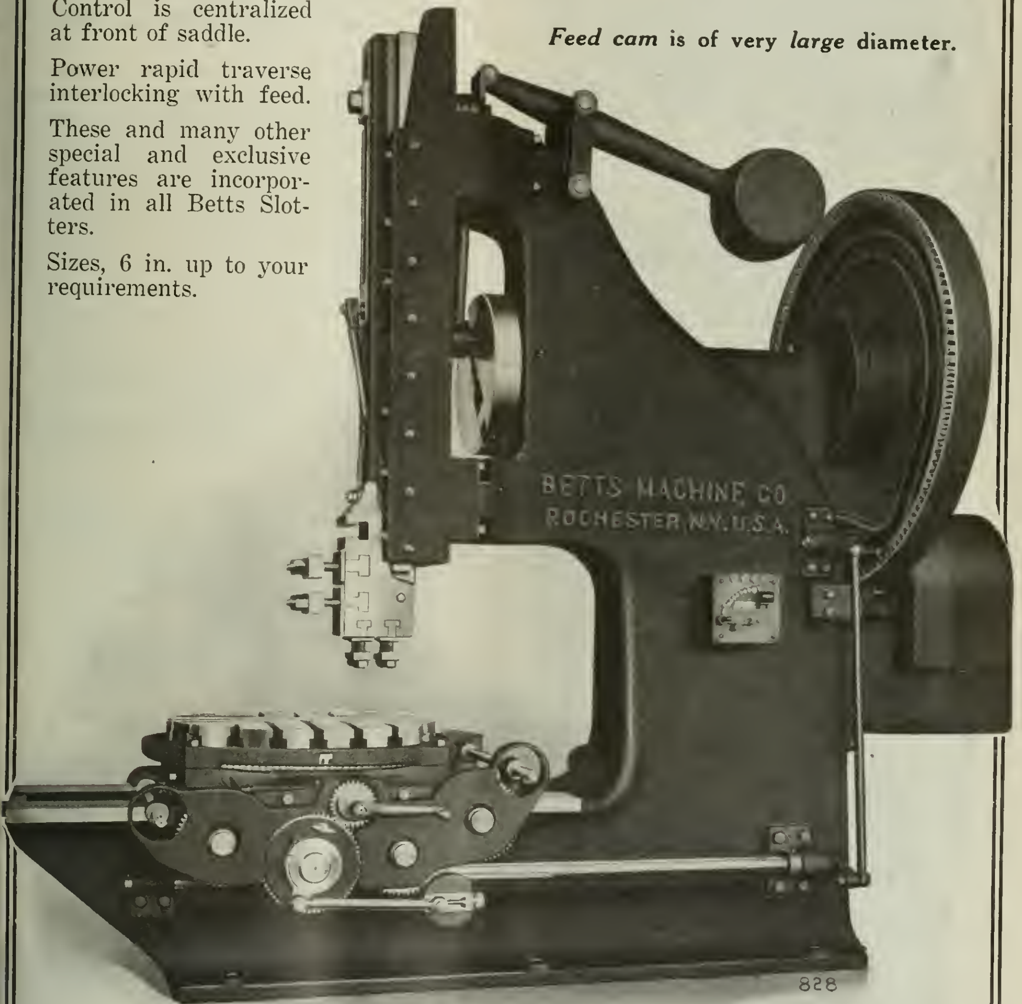
Control is centralized at front of saddle.

Power rapid traverse interlocking with feed.

These and many other special and exclusive features are incorporated in all Betts Slotters.

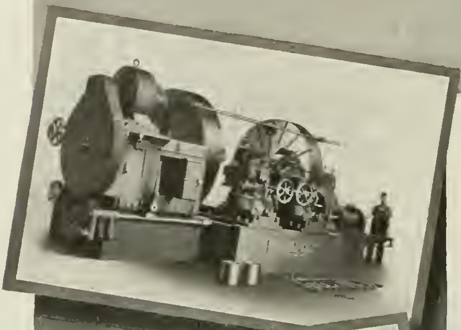
Sizes, 6 in. up to your requirements.

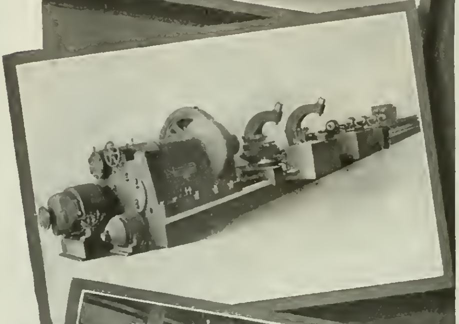
Feed cam **is of very** ***large*** **diameter.**

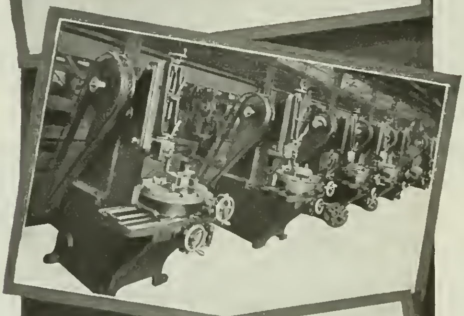


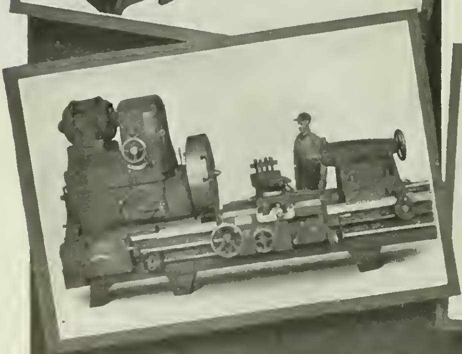
BETTS MACHINE CO., 400 Blossom Road, Rochester, N. Y.

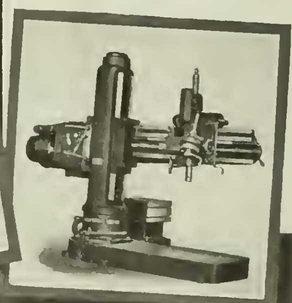
BETTS MACHINE TOOLS











Complete Machin

For General Manufacturin
Railway Shops, Shipyard

OUR eight factories, greatly enlarged and re-equipped within the past few years, are today manufacturing our extensive line of standard products to serve *all* your machine tool needs. We furnish *complete* machine tool and crane equipment for general machine shops, locomotive and car building shops, railroad repair shops, arsenals and shipyards. Our engineering departments have had wide experience in such installations and their services are at your disposal. We build

- Engine and Forge Lathes—7 in. to 170 in. swing.
- Gun Boring and Turning Lathes—for guns up to 20 in. calibre.
- Planers—from 30 in. to 20 ft. between housings.
- Boring and Turning Mills—30 in. to 45 ft. swing.
- Drilling Machines—all types and sizes.
- Slotters—6 in. to 92 in. stroke.
- Horizontal Boring, Drilling and Milling Machines—all types.
- Horizontal and Vertical Milling Machines—various types and sizes.
- Bending and Straightening Rolls.
- Punching and Shearing Machines.

Electric Traveling Cranes—2 to 250 ton capacity.

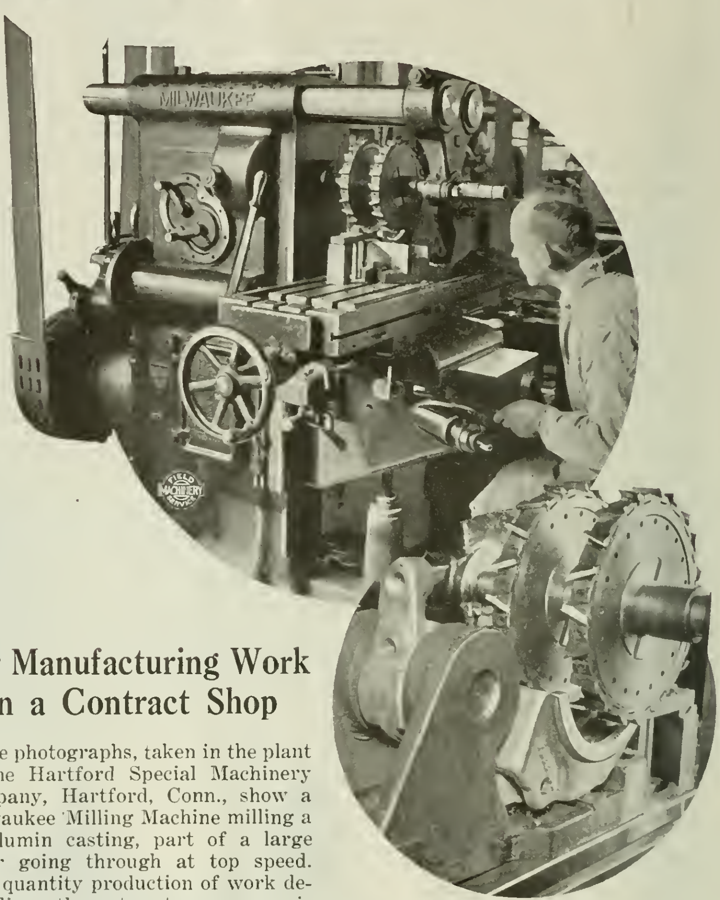
MILWAUKEE MILLING MACHINES



For Manufacturing Work in a Contract Shop

These photographs, taken in the plant of the Hartford Special Machinery Company, Hartford, Conn., show a Milwaukee Milling Machine milling a duralumin casting, part of a large order going through at top speed. This quantity production of work demanding the utmost accuracy is handled without difficulty; the range, accuracy and operating conveniences of Milwaukee Milling Machines make them particularly valuable equipment for manufacturing operations of this class.

There are nine Milwaukee Milling Machines here giving uniformly satisfactory service on all the varied milling operations that come up on contract work.

If your work includes milling—any kind—get the details of these machines.

LANDIS

At the Louviere (Belgium) Bolt Co. Works—Ten Landis Single Head Threading Machines in this Row

In addition to these ten 1½″ Landis Single Head Threading Machines the Louviere Bolt Company has two more machines of the same size and one 2″ Double Head machine, in another department. All of these machines are used for threading bolts; all are highly efficient and profitable; that they are entirely satisfactory to their owner is evident by the size of the installation.

If yours is a problem of cutting threads we'll be glad to put our engineering department at your command—no matter where you may be. Write us.

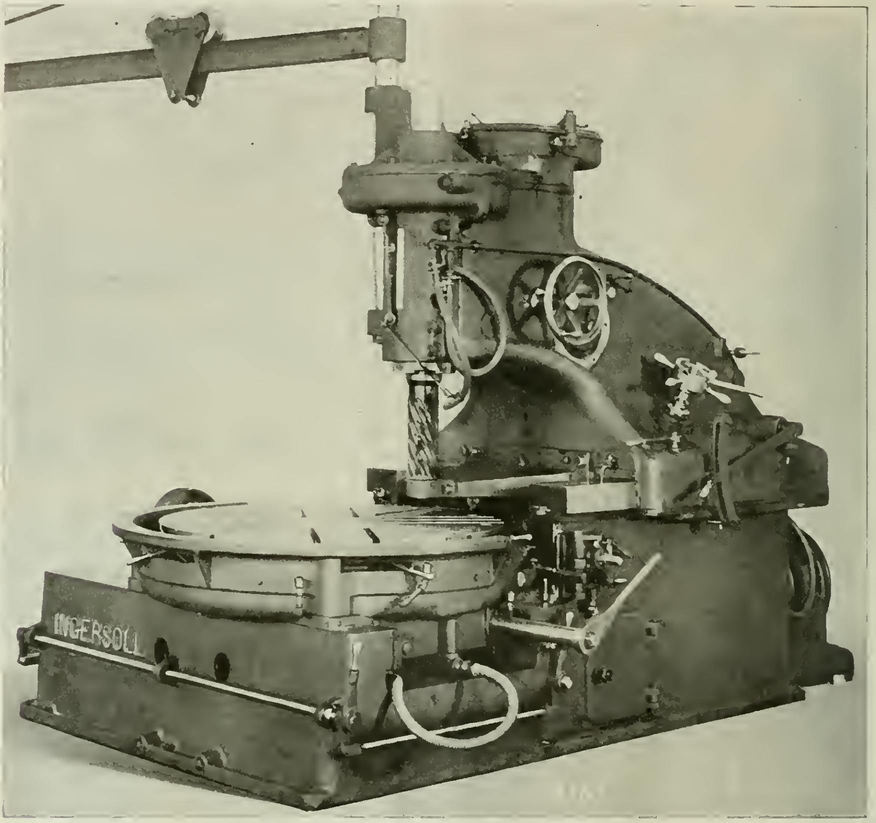
GRAY

INGERSOLL

Adjustable Rotary Milling Machine for Profile Milling, Face Milling and Die Sinking



The Ingersoll Adjustable Rotary Milling Machine is a tool developed for shops having a wide range of work. It can be used to advantage for profile milling, die sinking or face milling. It is invaluable in railroad shops for profiling locomotive rods and straps, milling out piston and strap ends of main rods and milling slots from the solid, etc. An exceptionally large combination of movements can be obtained from the head, housing, table and saddle of this machine.

The table rotates by hand or power on a saddle which in turn is mounted on wide ways of the bed and can be fed in either direction. The table and saddle can be locked together so that they form virtually a single casting.

The spindle is mounted in a housing which can be fed toward or away from the line of the table travel. The spindle has a vertical adjustment of 21 inches and is fitted with boring and drilling feed.

The control levers are all located so that the operator can reach them while watching his work. The jib crane on the machine is standard equipment and is of great value in setting heavy castings or forgings.

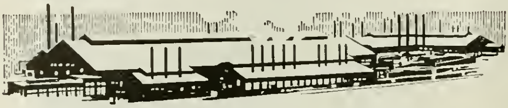
COLONIAL TOOL STEELS



The Colonial Mill at Monaca, Pa.

Jobs that are done well with *Colonial*

An interesting example:—for cutting tempered steel blades "Colonial No. 7 stands the job best."

THE BENEDICT MFG. CO.

EAST SYRACUSE, N. Y., U. S. A.

Colonial Steel Co.,
177 Hudson St.,
New York City.

Gentlemen:—

We are sending you today steel blades, and also two handles, which we are cutting up here with your Colonial No. 7 Cut Die Steel.

Mr. Peck says he has tried every kind of steel for these two jobs and finds that the Colonial No. 7 is the only Die which will stand to cut the standard hardened blade from a coil 7/8″ wide.

We cut 140 gross of blades and then grind the dies and repeat the operation. The dies are made in four separate pieces, to allow for the grooves which come on the cutting edge. These can be ground out by flexible shaft grinding, and the center recess shortened up. This makes the blades always the same length. The two outside pieces are Colonial No. 7, and the center pieces are machinery steel.

The handles are cut with the same kind of made up dies. The hot rolled scale on the handles is of course very hard on the dies.

No. 7 stands the job the best of any steel on the market anywhere near the price.

Yours very truly,

BENEDICT MFG. CO.

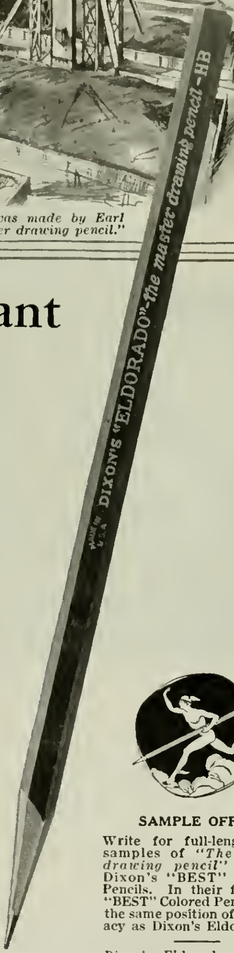
The pencil drawing reproduced above was made by Earl Horter with Dixon's Eldorado—"the master drawing pencil."



The Largest Steam Power Plant in the United States

The new Hell Gate Power Station of the United Electric Light and Power Company (shown above) was designed by Thomas E. Murray, Inc., of New York City.

When completed, it will be the largest steam power plant in the United States with an ultimate capacity of 300,000 K. W.

The plans for this plant, as for so many others of conspicuous size and importance, were prepared with Eldorado pencils.

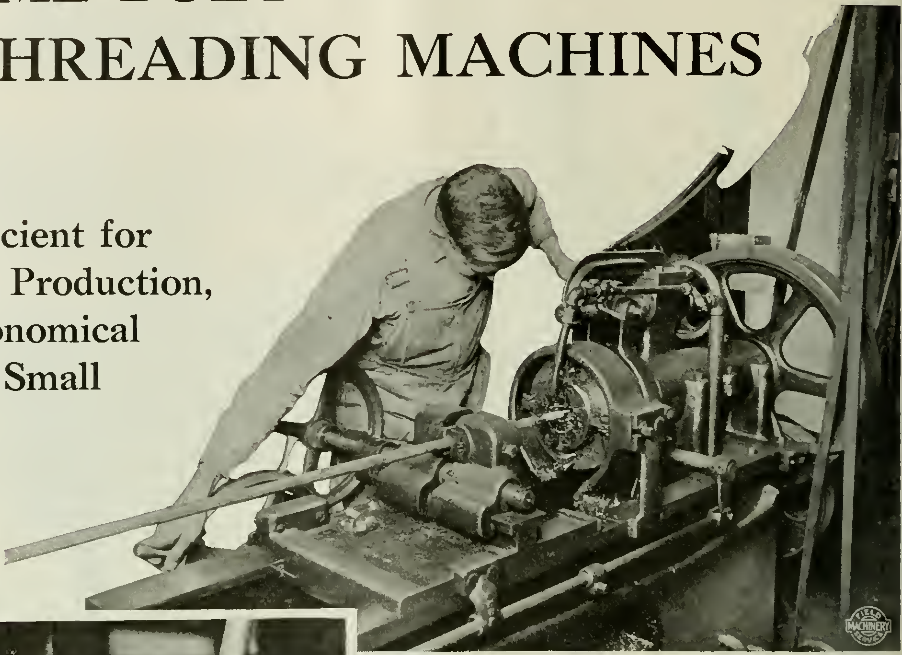
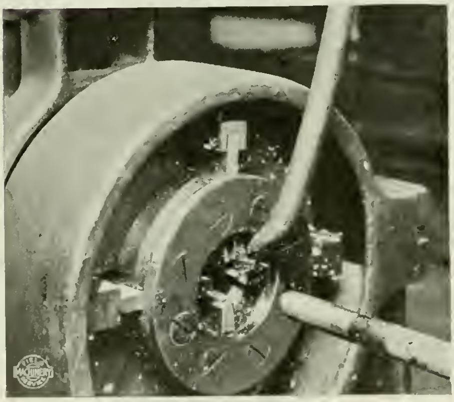
Write for full-length free samples of *"The master drawing pencil"* and of Dixon's "BEST" Colored Pencils. In their field, the "BEST" Colored Pencils hold the same position of supremacy as Dixon's Eldorado.

Dixon's Eldorado is made in 17 leads—for all pencil work.

ACME BOLT CUTTING AND THREADING MACHINES

Efficient for Big Production, Economical for Small





Photographs shown through courtesy of Herman Behr & Company, Brooklyn, N. Y. A 2″ Single Head Acme Bolt Cutter installed four years ago, cutting thread on end of a 3/4″ steel rod. By changing dies this Acme is used for bolt and pipe threading, accommodating any work up to 2″ diameter.

Acme Bolt Cutters and Threaders are designed for strength, durability and ease of operation. They are efficient for large production and economical for small—two characteristics which have won many orders for this equipment.

Another Acme feature is the lubricating method, insuring a generous stream of coolant to the dies at all spindle speeds. The Acme Die Head is simple, lasting and cheap to maintain. All wearing parts are of hardened tool steel ground to size.

We've printed a copy of our new catalog for you.

In 25 and 50 Ton Capacities

Wright Dieing Machines

Patented July 2nd, 1918.
Other Patents Pending.

The Wright Dieing Machine has pulled punch press work out of its rut and put it on a genuine manufacturing basis. The Wright is daily slashing costs, tripling output, revolutionizing manufacturing procedure and giving an entirely new meaning to production efficiency.

Punch presses have been in common use since the time the artisan first employed sheet metal as a basis of manufacture. For the past hundred years there had been but little change in the type or construction of presses for the use of blanking, forming, drawing, embossing, etc., of sheet metal until the Wright Dieing Machine appeared. The Wright has helped every user to turn over a new leaf—to increase production from 20 to 50 per cent.

The Wright's center of gravity is low. The flywheel and crankshaft being located beneath the dies. Power is transmitted to a lower gate or crosshead, guided on long ways taking both lateral and vertical thrusts. Four bronze bushed chrome nickel steel rods connect the lower gate with the punch carrying crosshead. This precludes torsional strains on upper crosshead, assures direct vertical pull at corners and the perfect alignment of punch and die otherwise only achieved with a sub-press.

Send for Descriptive Circulars.

Spline Shafts

The Spline Shaft has come into general use by reason of its wide adoption in automobile construction, where it has proven its practicability.

This adoption of the Spline Shaft has received further impetus by the development of two modern processes that have made it a practical manufacturing proposition—the pull broaching process and the hobbing process.

Hobbing Spline Shafts is the same in principle as hobbing gears—the work and hob both rotating, the cutting is continuous until the cut is finished. This eliminates the possibility of inaccuracy by distortion from localized heating in cutting and insures accurately indexed keys.

It should be as evident as it is actual, that no other process can equal the Hobbing Process in producing accurate Spline Shafts.

Submit your spline shaft problems to our engineers for solution. Our experience and research are at your service.

CAPACITY

THERE can be no doubt about the capacity of a Whitman & Barnes drill or reamer.

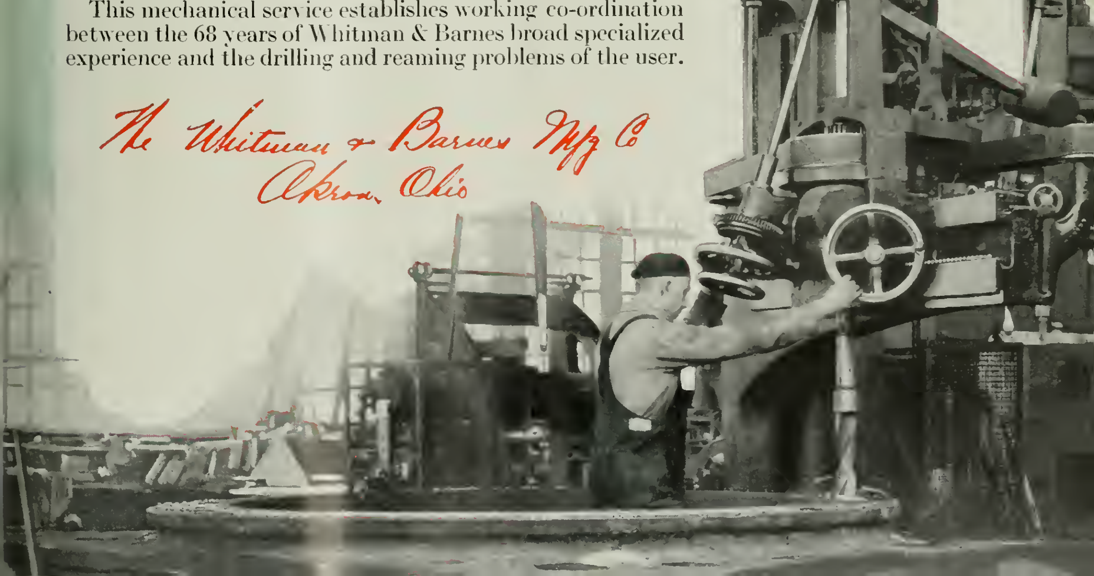
The makers of these tools know the technical history of American industry, as well as the needs and general requirements of modern manufacturing.

The inherent qualities in a "W & B" drill or reamer are so far in advance of these requirements that it is a question, largely, of selecting the proper "W & B" drill or reamer for the work to be done.

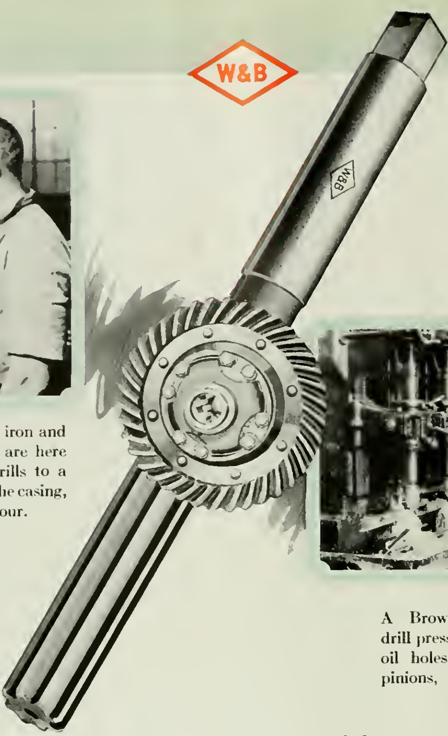
That is a partial explanation for the remarkable success of "W & B" mechanical service to the user.

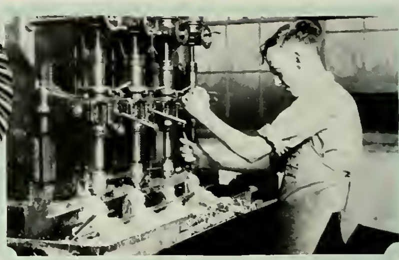
This mechanical service establishes working co-ordination between the 68 years of Whitman & Barnes broad specialized experience and the drilling and reaming problems of the user.

The Whitman & Barnes Mfg Co
Akron, Ohio

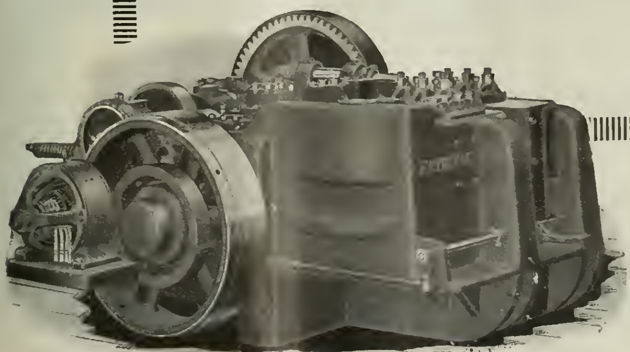


Brown-Lipe-Chapin malleable iron and steel forged differential cases are here being drilled with ¾-inch drills to a depth of ¾ inches, 4 holes to the casing, at a rate of 60 cases per hour.

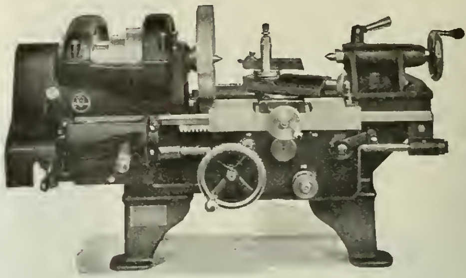




A Brown-Lipe-Chapin four spindle drill press with "W & B" drills, drilling oil holes in 3½% nickel steel side pinions, at a continuous rate of 350 pieces per hour.



Monarch Lathes Lead



All sizes and styles. Special equipment is furnished on all Monarch Lathes from 9-inch to 30-inch swing.

They are always manufactured in such large quantities that the production cost is kept to the minimum and the buyer saves in first cost.

The first cost isn't the only saving the buyer makes. *Repeat orders* from MONARCH USERS testify to the accuracy and lasting qualities of Monarch Lathes. The MONARCH factory is busy. MONARCH Lathes are selling. Investigate Monarch before buying any lathe from 9 inches to 30 inches in size.

From the little Monarch Junior 9-inch lathe weighing 500 pounds, to the massive 30-inch Monarch weighing 8500 pounds, there will be found a lathe meeting your requirements. And at a price you will consider very reasonable.

NATCO
In the Hupmobile Plant
Tapping
10 Holes in 10 Seconds
Counterboring
10 Holes in 20 Seconds
These two operations are done on the same NATCO, a No. 30. Hupmobile Cast Iron Crank Cases comprise the work. The holes are tapped ½ in. diameter and 1¼ in. deep; time, ten seconds. Another group of ten spindles counterbore ten ½ in. holes to ⅝ in. and ⅝ in. deep; time, 20 seconds.
The spindles on this NATCO are so arranged that the counterboring spindles are clear of the crank case when the tapping is done, and vice versa. Because of our patented Independent Change of Speeds the tapping spindles and the counterboring spindles are each driven at their correct speeds.
No matter what the character of your work is, if it is in the realm of multi-drilling the NATCO way will be of dollars and cents interest to you.
The National Automatic Tool Company
Richmond, Ind., U. S. A.

Battery Installation of New High-speed Gear Shapers. One 6-H.P. Motor furnishes Ample Power for Ten Machines.

Power Used to Overcome Friction is Wasted

It does not produce anything but heat, which in a production machine is wasted energy.

The new High-speed Gear Shaper is full ball bearing equipped, automatically lubricated, and with all reciprocating members light weight; therefore, the power consumed is unusually low.

A one H.P. motor furnishes more than ample power to operate a single machine at full capacity, whereas a six H.P. motor will easily fulfill the power requirements of ten machines.

Floor space required is one-third less than any other gear cutting machine having the same capacity.

The installation of a new High-speed Gear Shaper will undoubtedly reduce your overhead and production costs.

Give us an opportunity to prove it.

For Profitable Die Work

"Consider the Brass"

IN THE LABORATORY

The microscopic examination of a sample of brass makes it possible to see the inner structure of the metal at any desired magnification.

Durability, elasticity and *uniformity* are the factors that insure profitable production on this work.

The big punch presses operate with clock-like precision, but if the brass is not uniform, cracks, strains and other imperfections mar the work. Experience has taught us to produce good brass—Science enables us to make it uniform. That's why we consider our laboratory as important as any other part of the work. Only by the scientifically accurate tests made by experts working with highly sensitive apparatus can we tell why the brass we specify for a particular job will give the desired results; can we guarantee that the quality of future lots for the same purpose will *not vary*—though years separate the orders.

For uniform results in the matter of production and work—in other words, uniform profits—make sure of your material. Specify Chase Brass.

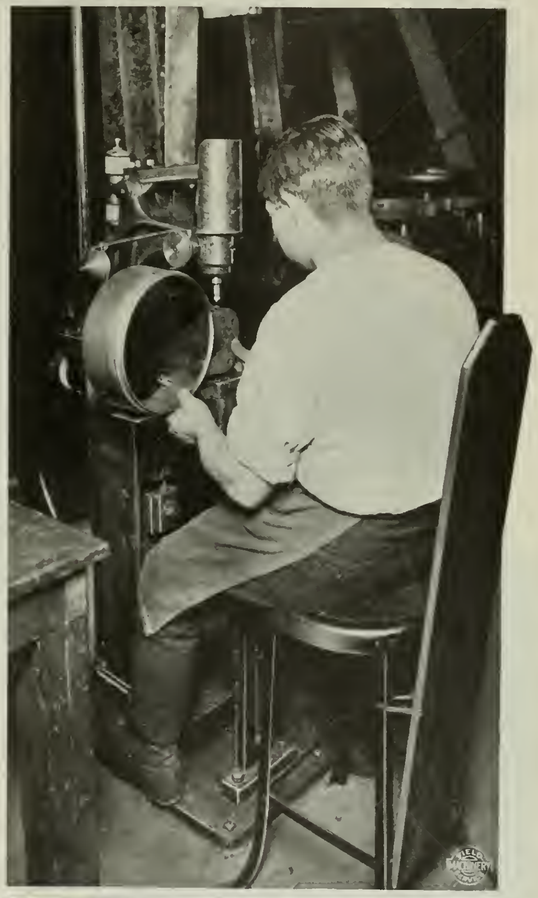
HIGH SPEED HAMMERS

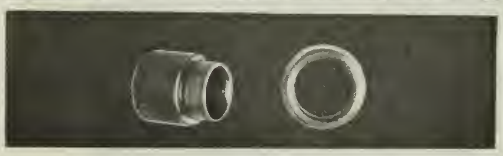
(PATENTED)

In the Famous "*Tycos*" Plant



In the world-famous "*Tycos*" factory one High Speed Riveting Hammer performs 300 riveting operations per hour. For ten years the machine in the picture has been at work in the Rochester, N. Y., plant of the Taylor Instrument Company—and it is still doing full duty.

The work shown is the case and partial assembly of a "*Tycos*" heat recording instrument familiar to all manufacturers engaged in the heat treatment of metals. The case is a brass stamping .064″ thick. In the small end of it, two brass shells with turned shoulders are inserted in holes, washers slipped over the protruding ends which are in turn riveted, fastening the tubes securely to the recorder case. Production is 150 cases per hour, which means assembling the shells and washers into position from 300 rivetings on the High Speed Hammer.



You will find it profitable to thoroughly investigate the efficient High Speed Hammer. It will serve you as well as it does "Tycos." Write us.

Prejudice *vs.* Profit

MANUFACTURING plants are very often located in the immediate vicinity of the moving spirits of the organization, without any regard to the advisability of the district being the best for obtaining raw materials, transportation, labor, power, etc., or of it being in the center of the greatest market in which the plant will distribute its product.

It is a well-known fact that large corporations thoroughly investigate every possible location before deciding where a new plant will be built. Their foresight has always resulted in a marked advantage over competitors and decided increases in *profits*.

Many organizations, believing that they have neither the time nor the money to spend on an extended investigation, fail to consider the advantages that can be secured by obtaining the data and statistics that the railroads have to offer on any section that they may be considering.

The railroads believe that their success depends upon the prosperity of the industries along their lines. They are therefore earnestly endeavoring to co-operate with the manufacturers in collecting all available data pertaining to different sites in order to assist the manufacturer in scientifically selecting the section of the country that would be *best* in which to locate any particular industry.

Some of the most pertinent data compiled by the Lehigh and New England Railroad Company on this subject, has been assembled in book form under the title, "Locating the Factory." A request on your business letterhead will bring you a copy without cost or obligation.

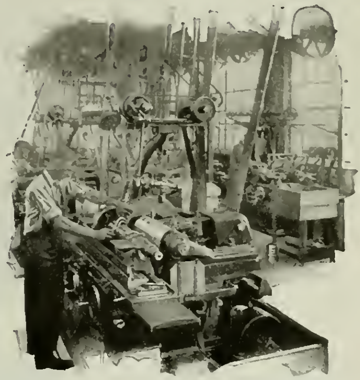
Grinding Accuracy in the Manufacture of STROM BEARINGS

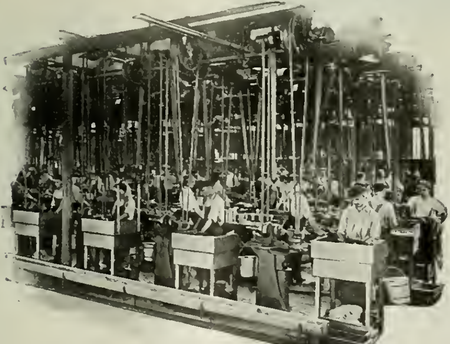
Bores, outside diameters, and widths are ground on precision grinders to limits measured within the ten thousandth of an inch, thereby insuring a uniformity of dimensions which enables the user to install Strom Bearings without further inspection or selection for his requirements.

Races are ground to true circumference and accurate contour. They have that smooth surface which is so essential to the reduction of friction.



Accurate Machine Tools and skillful workmanship are requisites in the manufacture of Strom Bearings

The Grinding Department is equipped for quantity production



These refinements are characteristics of the complete line of Strom radial, thrust and angular contact bearings.

Strom engineers are especially trained to solve bearing problems. They will be glad to work with you in determining the type and size of bearing that will give you the best results.

WATER BOX VALVE CAP

LIBBY LATHES

Saving Over $13.00 Per Hour

Here are facts and figures to show how this Libby Lathe saved $121.80 per day —more than $13.00 an hour for 9 hours. Look at the accompanying sketch. On each water box valve cap the Lucey Manufacturing Corporation, Houston, Texas, saved through this Libby installation 17½c. on labor. In labor plus overhead it saved 43½c. Production is 280 valve caps per day which puts the total saving per lathe at $121.80 or better than $13.00 an hour.

Suppose you could save this sum on your work! Do you know what you do save? Do you save *anything?* Tell us what you make; send blueprints; then, we'll write you. Libby Lathes are built for production and profit—your profit. Write us today.

Leave it to Libby.

BARNES RADIAL DRILL

Spindle Travel 18 inches
No. 4 taper hole in spindle
Weight 3,300 lbs.
Table 24" x 65"

WE illustrate herewith a No. 3 Horizontal Radial Drill or End Drilling and Tapping Machine. The machine is back-geared, strong and well built, and all parts are within easy reach of the operator. The table is slotted for holding the work; the arm is of heavy box pattern, and the sliding head is gibbed strongly on the square ways of the arm. For operating the spindle, the operator has choice of three feeds; namely, the lever feed or the handwheel feed or power feed. Power feed has positive drive.

Dimensions No. 3 Horizontal Drill:

Distance from top of table to center of bearing, 8¾ inches.

Center of bearing to maximum height of spindle, 38¼ inches.

Bearing, 9 by 12 inches long.

Spindle arm moves through circle of 180 degrees.

Face of arm, 8 x 9 inches.

Distance from table to center of spindle, maximum, 29½ inches, minimum 2⅜ inches.

Drilling capacity in solid C. I., 3 inches; steel, 2 inches.

Tapping capacity in C. I., 3 inches; capacity of pipe tap, 2½ inches.

We can furnish Arbor Rest (extra cost) which is adjustable both vertically and horizontally.

Introducing the—
Little Giant
PIPE WRENCH

On the Job

It gets into the holes and corners that the conventional pipe wrench can't touch. Look at the *end opening* jaws. They reach into cramped places just like a pair of pliers. They grip instantly and independently of springs.

This *"Little Giant"* Wrench *takes hold* and *lets go* quicker than any other wrench you ever used, and we can guarantee that.

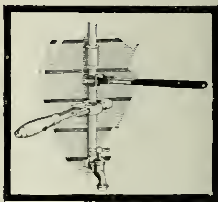
The Wrench Itself

It has just three parts. Two powerful drop forged jaws and a nut, all three carefully heat treated. No cumbersome frame, no springs, no rivets. The new patented design gives extreme strength. (The 14 inch size, for example, has repeatedly withstood stresses in excess of 4700 inch pounds—2800 is Uncle Sam's test.) Finally, it has *double* the life of an ordinary wrench, because the moveable jaw can be engaged with teeth on both sides of the solid jaw. (See illustration)

The *"Little Giant"* Wrench will be made in 8", 10", 14", 18", and 24" sizes. The three smaller sizes are now in stock for immediate delivery. Hundreds of users are daily expressing their satisfaction with this new wrench.

Let us tell you more about it.

ONLY THREE PARTS
Practically Indestructible
(Note teeth on both sides of jaw)



Showing the greater effective swing of the *"Little Giant"* Wrench when pipe is close to wall.

Wire Forming

Section of a Wire-forming Shop

First of Two Articles Describing the Methods Used in the Manufacture of Wire Goods and the General Principles Applied in the Design of Typical Wire-forming Machines

WIRE can be bent, twisted, curled, upset, or otherwise formed into innumerable shapes. Greater liberties may be taken in the manufacture of wire goods than in making articles from metal in any other form. The possibilities are not limited by any special sectional shape of wire, by any particular material, or by any physical condition of the wire except extreme hardness. Iron and steel wire of various degrees of hardness are commonly used, as well as copper, brass, bronze, and precious metals.

The mechanical means for forming the wire are essentially the same for all materials, but the peculiarities of shape make it necessary to employ some interesting methods in performing the work, and some extremely ingenious tooling for the machines is used. Nearly every conceivable shape can be produced in wire by the use of the familiar type of wire-forming machine, supplemented in some instances, particularly where ribbon stock is to be formed, by the power press.

The various machines in common use are designed to operate substantially in the same manner. They consist fundamentally of four cam-operated slides arranged 90 degrees apart; these advance to a common center at which point a vertical member, called the "king-post," is located. The king-post is the member around which the wire is shaped by the dies or forming members that are carried in the slides. Obviously, the range of service of the machine depends upon the ingenuity employed in laying out suitable cams and in setting up the job. Considerable variation from the four-slide arrangement is practicable, because it is possible to mount auxiliary cams on each camshaft for operating levers and additional slides, so that pieces requiring more than four bending operations can be produced by thus increasing the scope of the machine.

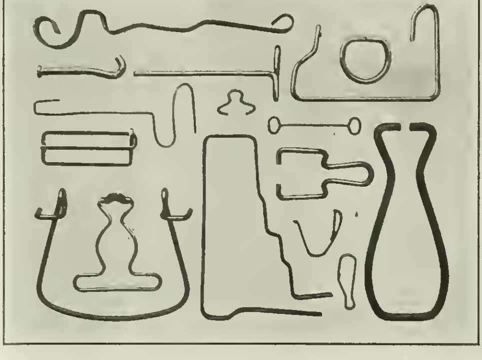

Fig. 1. Wire-formed Parts, showing Variety of Work

The forming dies themselves are simple in construction, and consist of finger members attached to the slides, usually provided with a groove at the end to receive and guide the wire as it is bent. Auxiliary levers are frequently interposed between the slides when extra bending members are required, and these are essentially of the same design as the dies except that they usually move independently of the slides. The grooves in the bending members are sometimes machined with wide mouths, so that the sagging wire may be brought against the angular surface and raised to the proper level, or the end of the wire may be brought to any desired plane to prevent interference with other parts of the wire, preparatory to the next operation.

The Eastern Tool & Mfg. Co., Bloomfield, N. J., whose practice is described in this article, has found it necessary to carry a great many different kinds of die steel on hand, in order to meet the requirements for manufacturing wire goods of varying material and design. Experience has shown that the design, as well as the kind of wire, affects the suitability of a steel for any particular die service. For a piece of work made from soft steel wire, having an average number of not too complicated bends, it is the usual practice to use 0.90 per cent carbon steel. Other steels commonly used for small spring wire work, which is particularly severe on the dies, and for forming hard wire and certain more difficult shapes, are chrome-vanadium and chrome-nickel steels. Widely varying compositions of each of these steels are regularly used, and they are, of course, carefully hardened and tempered, according to the specifications of the steel manufacturer.

The movements necessary to form a piece of wire into a more or less complicated shape may be varied in their sequence. The first consideration when a part is to be manufactured is the proper starting place in relation to subsequent operations. It has been found, even after large quantities of pieces have been manufactured commercially by one method, that greater production can be obtained by making certain simple changes which affect the entire cycle of the movements and completely revise the manufacturing procedure.

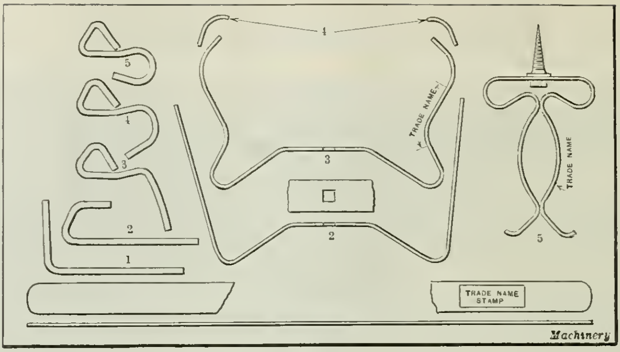

Fig. 2. Successive Shapes in the Manufacture of an S-hook and of a Holder made from Ribbon Stock

Order of Operations and Design of Tools

After the design of the piece has been studied and the number of operations required to produce it has been determined, it is necessary to arrange the order of operations and design the tools for each. If a complicated piece is to be made the use of auxiliary tools actuated by one of the regular slide movements should be considered. For example, it is common practice to use bellcrank levers as auxiliary forming members, and it should be the aim to operate these in the simplest manner possible. Although this may be done by the use of an extra cam, it can often be more simply accomplished by designing one end of the lever with a cam surface and the adjacent die with a suitable cam rise.

Again, if a curling or heading operation is to be performed, care should be taken to provide a temporary support for the comparatively slender wire. This may be advantageously accomplished by designing the cams so that the side tools will advance against the wire and remain there while the curling or upsetting die is in operation, thus holding the wire rigidly and preventing it from buckling under the end thrust. This is one method that has been successfully used, but the most available facility should, of course, always be utilized. It might even be desirable to design the curling or upsetting die with an extending member that will bear against the side of the wire and in this way steady the stock, but such a practice depends on the space available for auxiliary members.

The slides are regularly referred to as front and back slides and side slides. Most wire articles would naturally be produced by first operating the front die, although the peculiarities of design may be such as to make it advantageous to reverse the order and actuate the front die last, as is sometimes necessary in the manufacture of links and specially shaped hooks. In making wire goods from certain kinds of wire, such as spring wire, for example, allowances must be made for an over-travel of the stroke of the slide, which will take care of the natural spring in the wire, so that when it becomes set it will have the proper shape. The design of the work will suggest methods of forming it, and it will not be found difficult to arrange the tools so that they can work in different planes, if necessary.

Production may be facilitated by the ingenious design of the king-post. If a piece like a clasp is to be made, it is frequently possible to produce tension where the ends meet, by designing the king-post so as to make a bulge in the work, which may afterward be automatically straightened as the work is stripped from the king-post, and thus bring the two ends together in tension. Extensive application is made in wire bending of this principle of obtaining spring tension. In designing the king-post, it is well to consider what surfaces may be subjected to excessive wear, and to construct the king-post in sections that may be replaced.

Provision for Elevating the King-post

The king-post is usually assembled rigidly in the machine, but certain designs of wire goods make it desirable to provide for raising the king-post, as the final operations cannot be performed if the king-post remains within the formed work. A case of this kind is where flat stock is to be folded into a T-shaped paper fastener and it is necessary to elevate the king-post in order to permit closing the stock.

The grooves in the ends of the dies may be staggered or offset; by arranging these grooves properly in the various dies of a job, slight bends may be made, without regard to the direction of the sharper bends formed as a result of the slide movements. In forming an article that lies in one plane, it will commonly be found that the opposite ends of the wire will interfere, and some method must be used to displace one end temporarily while the other end is being bent over or under, as the case may be. This is sometimes done by attaching to the side of a die a separate piece which has an angular end so that the wire may ride up its inclined surface;

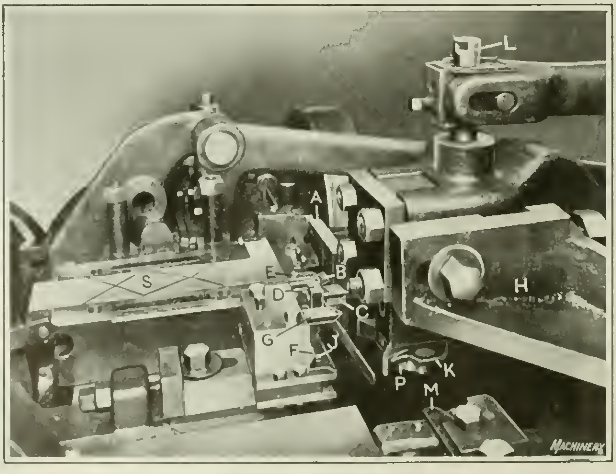

Fig. 3. Right-hand Side of a Wire-forming Machine equipped with a Punch Press Attachment and Dies for forming Ribbon Stock

or the interference may be avoided by using a sliding member to operate in the stationary king-post and bear downward against the wire.

It is often advisable to utilize the cut-off for a double purpose. The cut-off tool can be designed so that with one movement of the cut-off mechanism the stock will be severed and the end bent at the extreme downward travel of the tool. Sometimes this bend can be taken care of by attaching a separate piece to the side of the cut-off, especially if the bend to be produced is a considerable distance from the severed end of the stock.

It will be seen from the few phases of wire forming mentioned that the possibilities of varying the tooling arrangement to meet special conditions are numerous—so numerous, in fact, that it is impracticable to attempt to include all operating conditions here. Some of the points mentioned will now be brought out in describing the manufacture of a few articles of familiar design. The methods described have been selected with a view to presenting a rather diversified line of wire goods manufacture.

Forming an S-Hook

The S-hook shown in the upper left-hand corner of Fig. 2 is a simple example of wire forming without the use of auxiliary slides or special mechanical movements. As will be seen by the numerals, this hook is completed in five bending operations. The hook is made from No. 14 W & M gage (0.080 inch diameter) soft steel wire, tinned. The work is performed in a Nilson No. 0 four-slide wire-forming machine, in which it is first cut off and bent as shown, by a cut-off tool made in two parts; one part severs the stock and the other forms the right-angle bend. This is a case where the front die does not come into action first, and the reason for this will be readily understood by an inspection of the shape of the work and by following the description of the operations required to complete it.

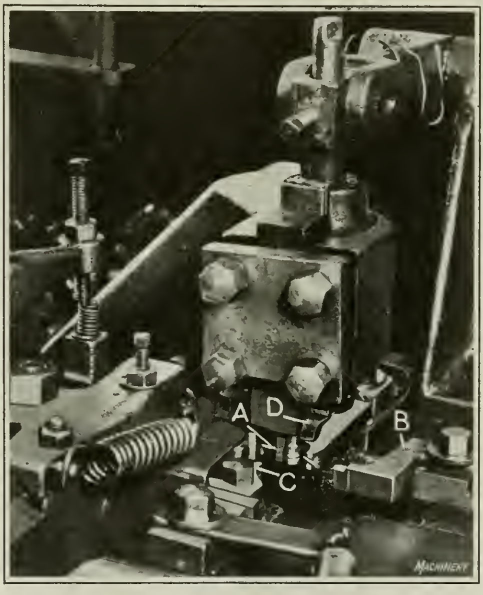

Fig. 4. Top of Wire-forming Machine showing Arrangement of Die-slides for making a Hook

The king-post has two separate members at its lower end, shaped to correspond to the loops in the hook, and the wire passes between these two members. The die on the left side of the machine then advances, bends the left end in the second operation, as shown, and recedes. The back die closes the triangular loop, and at the same time starts the bend for the hook end, but it cannot bend the hook end further than shown, on account of its position relative to the king-post. The right-hand die is next operated to produce the fourth shape shown in the diagram. This is the operation illustrated in Fig. 4. Here the position of the wire as it passes between the two members of the king-post may be seen at *A*, as well as the goose-neck shape of the side die *B* used to make the bend in the hook, which is offset relative to the loop in the opposite end.

Finally, the front die *C* advances and closes the hook end around the post, which completes the forming of the S-hook. The downward stroke of stripper *D*, which surrounds the king-post, then removes the work. Special designs of strippers may be employed to aid in forming the wire, as well as in removing it from the king-post, which will be referred to later. These S-hooks are produced at the rate of 7500 per hour, which is considered a very satisfactory production.

Flat Wire Forming

The manufacture of wire goods from ribbon stock may be properly classified as wire forming, but this work must often be supplemented by the use of a power press. Ribbon stock is handled in cam-operated slide machines of the same general type as those used for wire of other sectional shapes, and the tooling is not very different except where affected by the special design of the work. It is quite common, when ribbon stock is being worked, to employ a punch press attachment on the wire-forming machine, besides the regular slides. This makes it possible to perform many operations that would otherwise require a separate machine.

The piece shown at the right, Fig. 2, is a "three in one" holder suitable for suspending mop sticks and similar household articles. It is made from ½- by 0.041-inch extra-hard cold-rolled ribbon stock, and is stamped with the trademark, punched with a square hole and formed into the fourth shape shown in a Nilson No. 4 wire-forming machine equipped with a punch press attachment. This machine and set-up used for this operation are illustrated in Fig. 3. The slide *S* of the attachment (which has been exposed to view by the removal of the cover) is essentially the same in design as the slide of a power press. It is operated by a cam on the camshaft at the front of the machine.

The stock is fed in to a stop, and held in the correct relation to the dies by guides on the back-plate *A*. The back-plate corresponds to the bolster-plate on a power press. At one stroke of the punch-press slide the stock is cut off with rounded ends and stamped. The stamping die *B* and the cut-off punch *C* are located on the back-plate and are stationary. The cut-off die *D*, which produces the rounded ends on the stock, is attached to the slide member, and a piece of flat stock *E* is fastened directly above the die, extending forward and hooking down over it so that when the slide is advanced sufficiently the stock will pass between this piece and the face of the die. The purpose of this is to carry the end of the incoming stock backward after the blank has been cut off, and prevent its rounded end from catching in the curved surface of the punch.

The front bending die *F*, which is located in a slide at the right of the punch press attachment, then immediately comes into operation, bending the work against the plate *P* at the lower end of the king-post, to produce the second shape shown in Fig. 2, and at the same time punching the square hole. This hole must be located centrally in the stock. As wear is bound to occur in the slide, in order to locate the work accurately relative to the punch an auxiliary guide is employed in the form of a locating post *G*, shaped similar to a lathe center, which enters a bushed hole in the king-post. Wherever a king-post is used as a die-holder, as it is in this case, it is advisable to provide an additional bracket on the machine to support the king-post under the thrust of the punching operation. Such a bracket is shown at *H*. The end of the punch can just be seen at *J*. The die for this punch is a separate steel block having a suitable bushing carried in the king-post.

The steel plate *P* is designed on the sides as required to produce the third shape, and the two side dies (one of which is shown at *M*) advance together to form the wire to this shape. It will be noticed, from Fig. 2, that a separate operation is required to turn in the ends of the stock. This is necessary because, in order to produce a permanent set in these ends, the bending pressure must be applied at right angles to the direction of movement of the side slides. The back die which is used for this operation is a plain rectangular-shaped member which contacts only at the ends of the stock. The formed wire is then removed from the forming plate by a stripper *K* of special shape, which, like most of the stripping mechanisms used on this kind of machines, is actuated by a cam that moves the post *L* by a cam-lever.

Power Press Bending Fixture for Ribbon Stock

As has previously been mentioned, the forming of flat stock often requires the supplementary use of a power press. Although the punch-press attachment for a wire bending machine can be made to perform all ordinary punch press operations, where a bend is to be made in comparatively long pieces of formed stock requiring considerable space for the sweeping ends it is usually advantageous to perform the work on a separate press.

A case in point is the final bending of these holders, and the equipment used on the power press for this operation is illustrated in Fig. 5. Here it will be seen that the ram of the Sidney press used carries two vertical posts in which rack teeth are cut to revolve two pinions in the base of the fixture and turn the bending cams *A* which are attached to the same shafts that carry the pinions. These cams are in the form of collars with projecting lugs *B* which bear against the work at the beginning of the operation in the manner indicated in the illustration. Previous to this final bending a square-shank wood-screw is assembled into the square hole punched in the work and headed over; use is made of this screw to locate the work symmetrically when bending. The screw is straddled by a slotted post *C* in the fixture, and two pins *D* extends from the base so that, when properly located, enough tension will be produced in the work to hold it rather tightly.

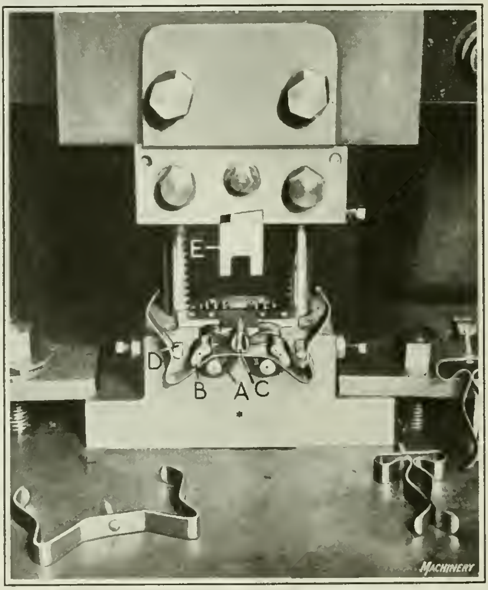

Fig. 5. Bending Fixture used on a Power Press

The bending operation itself is simple, and is of interest only in showing the transformation in shape which it is possible to realize by ingenious designs of bending fixtures. The downward stroke of the press ram results in lugs *B* bending the stock downward around the center posts, and sweeping the ends of the work around until the final shape is obtained. At this point the lugs, of course, are close together and shape the stock so that it touches directly below the head of the wood-screw. There is a tendency for the upper straight part of the stock to bulge outward due to this bending movement, so that an auxiliary die member *E* comes in contact with this part of the stock at the completion of the bend, and removes any bulge that may have been formed. An hourly output of 700 holders is attainable with this fixture.

The application of other principles of wire forming will be described in the second installment of this article, which will be published in September MACHINERY. Work of a more complicated nature will be described and illustrated, and views of the machines used and tooling lay-outs will be shown.

ACCURATE DESCRIPTIONS OF EXPORT SHIPMENTS

The Bureau of Foreign and Domestic Commerce of the Department of Commerce states that many glaring errors have been discovered in the statistics of exports for the first months of 1922, compiled under the new export classification which shows quantities in addition to values for every class. The records for previous years probably contained similar errors covered up in classes showing values only; for example, one lathe chuck at $3800 is mentioned; grinding and sharpening machines at $5 each, etc.

Investigation of the errors has disclosed that the majority are due to inaccurate description in the export declarations presented by the shipper or his agent at the custom house for clearance. Frequently inquiries have to be made at a great loss of time through collectors at distant ports in order to reach the original shipper and obtain accurate information for correction of the original reports.

One cause of inaccuracies is the practice of exporters to leave the preparation of the export declaration to forwarders or brokers at the port of exportation. The declaration should be prepared at the original point of shipment by a person having personal knowledge of the shipment. Preparation of export declarations should not be left to inexperienced clerks, who may not have a proper conception of its importance and regard it as a mere formality necessary to obtain customs clearance.

Exporters are urged to insert in the column headed "Class No. of Schedule B" on the declaration the number of the "Statistical Export Classification of 1922" under which they think the goods should be classified. This classification may be obtained upon application to the Bureau of Foreign and Domestic Commerce, Department of Commerce, Washington, D. C. Treasury Decision 38410, containing regulations regarding filing of export declarations will also be furnished upon request. Compliance with these suggestions will eliminate the principal source of errors, facilitate compiling, and increase the value of the statistics to exporters.

The American Engineering Standards Committee has decided to undertake the development of a safety code for conveyors and conveying machinery. The National Bureau of Casualty and Surety Underwriters and the American Society of Mechanical Engineers have been appointed joint sponsors for this code.

CAVITY DRILLING TOOL FOR ENGINE CYLINDERS

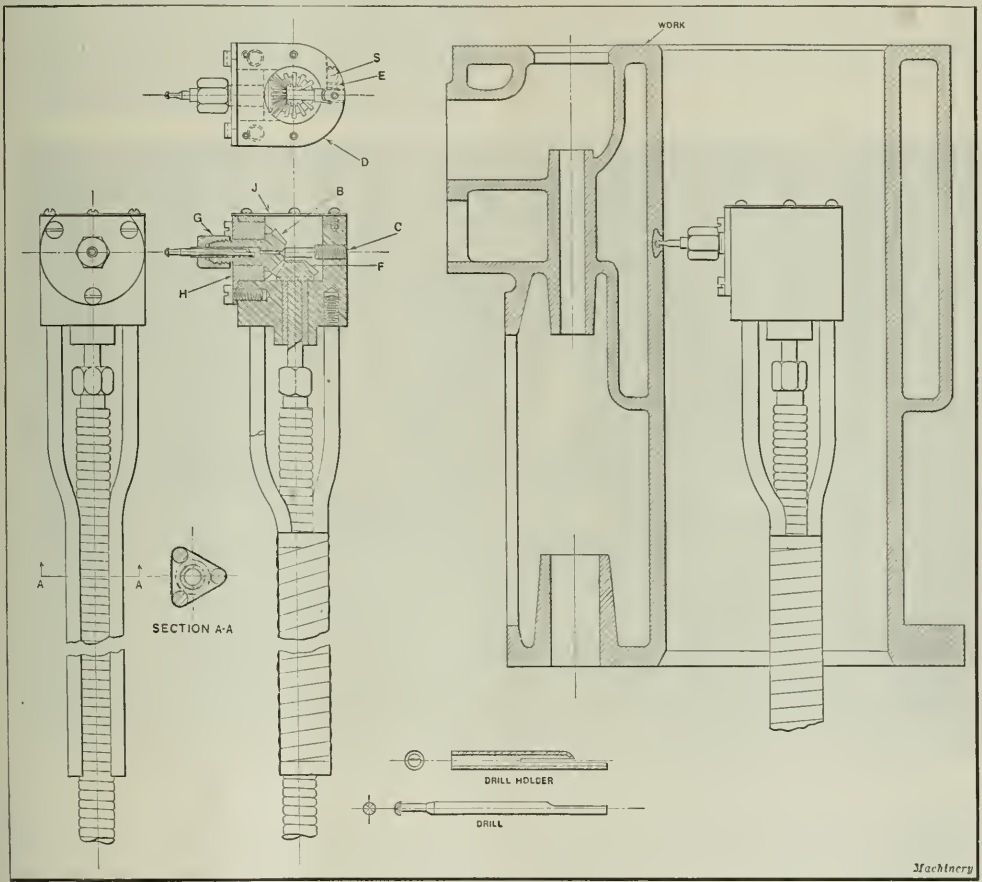
By CLARENCE M. SCHLEH

In the production of automobile engine cylinders it is customary to perform some of the machining operations before the final boring or grinding of the cylinder bore takes place. After the bore has been finished, the inspection department often finds little sand-holes or defects in the walls of the cylinder which could not be detected in the rough casting. In such cases the time spent on the former operations is entirely lost if no effective means of overcoming the defects are employed. Cylinders with defects of this kind, however, can be saved with little expenditure by cleaning out the cavities and then filling and closing them in by welding. The special drilling tool here illustrated has proved to be satisfactory for cleaning or drilling out the cavities preparatory to closing them in by welding. The cavity drilling machine is simple in construction and arrangement. It is equipped with miter gears which drive the drill, the gears, in turn, being driven by attaching the stem of one gear to the flexible shaft of a portable electric drill.

The drill itself is of a special design, of the type employed by dentists, as is shown in the small detailed view at the bottom of the illustration. This drill is slipped into the drill-holder, which is merely a small steel tube, the inside diameter of which fits the drill body. The holder is slotted at the rear end, and the upper portion is bent over and acts as a driver on the flattened end of the drill shank. The slot in the drill-holder gives it the spring tension required to hold the drill in place. A small chuck for holding the drill is provided by cutting a thread and turning a taper on the small end of gear *B*. Three slots spaced 120 degrees apart are cut in the end of the shank of gear *B*. When the hexagon nut *G* is drawn up tight, the tapered seat at the end of the threaded portion causes the slotted end of gear *B* to grip the drill-holder. Gear *B* has a flanged bronze bearing *H* which is held in place by three fillister-head screws.

At the large end of this gear is a center hole which fits the tapered end of the thrust screw *C*. This screw is inserted in a threaded hole in the gear-box *D*, being located directly opposite, and in line with, the gear center. The thrust screw is screwed in until the proper adjustment is obtained. It is then locked in place by the brass plug *E* which is pressed against it by tightening the headless setscrew *S* placed at right angles to the thrust screw. The driving gear *F* has a long shank, the diameter of which is turned to fit the chuck on the end of the flexible shaft of a portable electric drill. This gear is also provided with a brass bushing which is pressed in to the bottom of gear-box *D*.

The gear-box is made of a piece of cold-rolled steel stock, and is counterbored at the top to receive the driving gear *F*. A hole is also bored at right angles to that provided for the driving gear to receive the driven gear bushing *H*. The back of the gear-box is rounded, as shown in the plan view, to



Tool for drilling out Sand-holes or Other Cavities in Automobile Engine Cylinders permit a greater working space. The size of the gear-box is limited by the diameter of the cylinder, and must be made small enough to permit proper manipulation of the tool. An oil-tight gasket is placed under the flange of bushing *H*. After the gears are put in place and screw *C* properly adjusted, the gear-box is packed with grease. The cover *J*, is then screwed down on an oil-tight gasket.

Three threaded cold-rolled steel rods are screwed into tapped holes in the bottom of the gear-box. These rods are made so they will extend beyond the casting far enough to form a handle. These rods are bent inward and placed against the outside covering of the flexible shaft of the electrical drill. The three rods and the flexible shaft covering are wrapped together with tape as shown at *A–A*. It is necessary to make the handle longer when the tool is to be used for cylinders not of the detachable-head type, as the drilling tool in such cases can be entered at only one end.

The view at the right-hand side of the illustration shows the manner in which the tool is employed to clean out a cavity in a cylinder. When the defect in the cylinder is located, the drill is placed in the cavity and after being properly entered is shifted or manipulated in such a manner as to form a pocket beneath the surface, which is larger than the opening of the cavity. This is accomplished by means of the specially designed drill point. When the pocket has been cleaned out sufficiently, it is welded shut, being completely filled in with metal. As the maximum thickness of the cylinder wall is about 1/4 inch, care must be taken not to drill too deep. This may be easily avoided by securing the drill in its holder in such a position that only the allowable working depth protrudes. The end of the holder will then suffice as a stop for the drill. The enlarged pocket beneath the surface of the cylinder prevents the metal from working out should it by any chance become loosened. By this means the danger of doing severe damage to both the cylinder and the piston, is eliminated. The surface of the cylinder wall where the cavity is closed in is carefully smoothed off and the cylinder given a final boring or grinding operation. Thus the time, labor, and cost of the preliminary machining operations are not a total loss.

TOOLING FOR PITCHER PUMP CYLINDERS

Some very interesting special machine equipment and tooling for finishing the interior of pitcher pump cylinder castings is employed by the Goulds Mfg. Co., Seneca Falls, N. Y. Fig. 1 shows a battery of Prentice drilling machines tooled for boring, reaming and facing the small end of these castings. Instead of using the regular drilling machine table, the vertical ways of the drilling machines are equipped with a special clamping and supporting device, which is operated by handwheels at the sides. The castings are inverted and located on a seat *A*, which is clamped in the lower jaws by means of the handwheel at the left. This handwheel operates an opposite-hand screw so that both jaws are moved simultaneously.

The jaws are provided with outboard supports in the form of posts, and after this cast-iron seat has been set up for a particular size of pump casting it is not changed. The small end of the casting is clamped by a pair of jaws at the top that are operated similarly to the lower jaws, this arrangement assuring a true vertical position for the work. The seat is so located in the lower jaws that the work is properly aligned with the combination boring-bar. The upper clamping mediums are also provided with posts to support them.

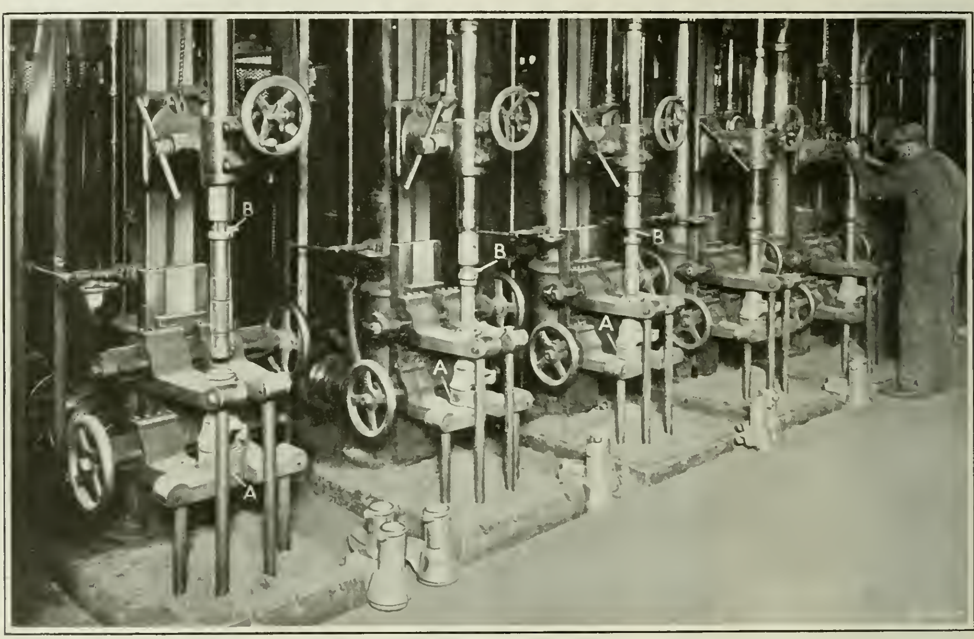


Fig. 1. Battery of Drilling Machines with Special Equipment for boring and facing Pitcher Pump Cylinders

A special extension boring-bar is used which has at the end five steel bits for stocking out the rough castings. After these have fed into the bore a few inches, three blades just above the stocking cutters finish-ream the holes. These two sets of cutters feed down through the casting until a fly-cutter *B* near the shank of the tool faces off the end of the casting. Directly under this cutter there is a floating collar which fits the finish-reamed hole preparatory to facing so that the end will be finished square with the cylinder bore. There are eight machines in this battery equipped as described, and they are all operated by one man who, by arranging the feed of successive spindles properly, may go from one to the other loading and unloading without loss of time. By this means a production of from 700 to 850 castings is attained in a nine-hour day.

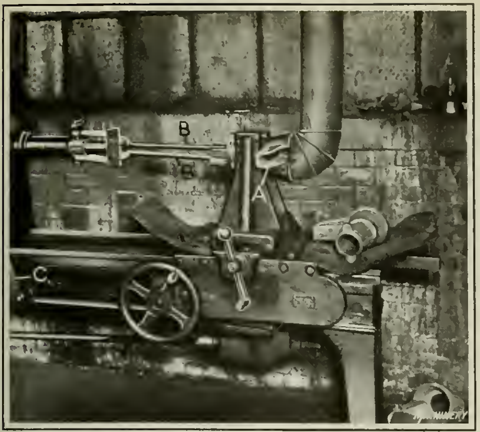

Fig. 2. Lathe equipped for grinding the Bores of Pitcher Pump Cylinders

The pitcher pump cylinder castings are ground on the bore with the lathe tooling shown in Fig. 2. Here it will be seen that the pump casting *A* is clamped in position, and aligned with the spindles of the machine by two special high cast-iron jaws. These jaws are operated by an opposite-hand thread cross-feed screw actuated by the handle shown at the front of the lathe. This entire unit—jaws, cross-slide, and apron—is special equipment applied to this lathe bed. The polishing tool consists of two pivoted arms *B*, on the end of each of which there is attached an emery pad. The arms are loosely held in a suitable holder in the machine spindle, and the pads on the extreme end may be spread to suit the diameter of the work being ground, by a screw adjustment at the opposite end of the arms. In grinding the work, the operator first closes the ends of the arms so that the pads will enter the hole in the casting and then advances the special carriage that carries the work, by means of lever *C*. The carriage movement is actuated by a rack and pinion.

The centrifugal force produced by the revolving spindle causes the arms carrying the emery pads to spread radially outward, so that as the carriage is fed toward the machine spindle the hole is ground. An exhaust pipe fits into the top of the cylinder castings to carry away the cast-iron dust produced in this operation.

THE WORLD'S MACHINERY TRADE

The present position of Germany as a competitor in the world's machinery markets has been considerably over-rated, according to William Althoff, assistant chief of the Industrial Machinery Division of the Department of Commerce. Mr. Althoff has compiled a review of the world's machinery trade in which he shows that while Germany held the first place in machinery exports from 1910 to 1913 inclusive, the United Kingdom following second and the United States third, in 1920 the United States ranked first, the United Kingdom second, and Germany third; and in 1921 the United States and the United Kingdom were practically on par, with Germany third.

The United Kingdom alone of the four leading machine exporters—the United States, the United Kingdom France, and Germany—shows an increase in its exports in 1921, due mostly to large shipments of textile machinery. Although the machinery exports from the United States fell off considerably during 1921, in value they exceeded the exports in 1918, and were more than twice as great as the exports in 1913. The value of machinery shipped from Germany in 1921 was only two-thirds the value of the machinery exported in 1913.

Fundamental conditions at present existing in Germany are such as seriously to impair its position as a competitor in the world's machinery markets. To a large extent present low costs have been the result of direct and indirect government subsidies which the German Government must necessarily abandon. Government control as applied to grain prices has already been abolished, bringing about a general movement for higher wages. Freight rates and raw material prices are rising rapidly, and labor difficulties are becoming increasingly numerous; and there is a shortage of both coal and coke. These and other factors make it practically impossible to quote firm prices for long-term commitments. The tendency now is to quote prices subject to increases to cover any enhanced production costs that may occur before the goods are delivered.

The complete review together with tables showing the exports from the four leading countries mentioned may be obtained upon application to the Industrial Machinery Division, Bureau of Foreign and Domestic Commerce, Department of Commerce, Washington, D. C.

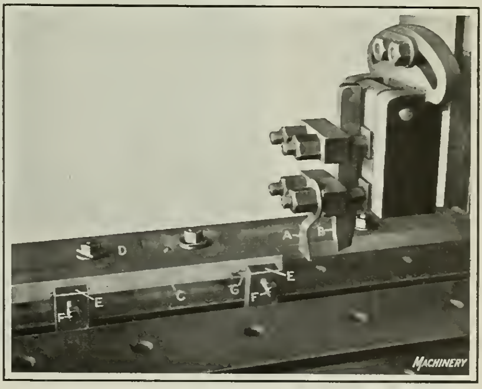
PLANING MEASURING MACHINE BARS

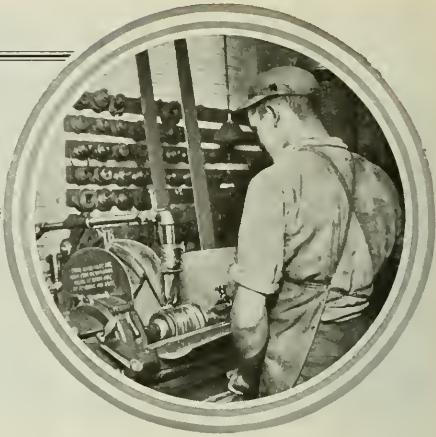
On the Woodward & Powell planer, which is shown in the accompanying illustration, engaged in machining bars for Pratt & Whitney measuring machines, the chief point of interest is the application of a sheet-metal brush *A* which runs over the work ahead of the cutting tool to remove chips from the surface, so that there is no tendency for the tool to ride up over the chips and cause them to roll and damage the surface of the work. The illustration does not show clearly the form of the cutting tool *B* used on this job. The impression might be gathered that this tool cuts with its narrow end surface, but as a matter of fact the cutting edge extends along the broad surface at the rear of the tool, as it is shown in the illustration, and this edge is inclined at an acute angle to the direction of the table travel in order that it may have an efficient shearing action and produce a smooth finished surface on the work.

A string of castings *C* is clamped against a parallel bar *D* that runs down the center of the table, the same arrangement of stops *E*, clamping bolts *F* and "butters" *G* being employed as in the case of the slide gibs. Only one cutting tool is employed, but two rows of measuring bars are set up on the planer table, as experience has shown that time can be saved by setting up a large number of pieces of work, so that while they are being machined the operator can attend to one of the other planers in the department. On this job the depth of cut is 0.006 inch, as it is desired to obtain a very fine finish. The feed is 1/8 inch per table stroke, and the cutting speed 25 feet per minute.



Finish-planing Operation on Pratt & Whitney Measuring Machine Bars

Grinding in the Automotive Industry



Methods of Grinding Steel Balls and Ball Bearing Races—Grinding Roller Bearing Cups, Cones and Rollers—Second Article of a Series

By The Engineering and Educational Departments
of the Norton Co., Worcester, Mass.

IMPORTANT grinding operations, such as are commonly encountered by manufacturers in the automotive field, were dealt with in the preceding installment of this article in July MACHINERY. Many of the parts used in the automotive industry, such as ball and roller bearings, springs, wheel rims, etc., are purchased by automobile manufacturers ready for assembling. Grinding as applied to the manufacture of these parts constitutes as important a series of operations as those in the automotive manufacturing plants, and grinding processes are employed for the same general reasons. In the case of such parts as ball and roller bearings, all of the finishing operations after hardening are done by grinding, because this is the only economical method of obtaining the required finish and accuracy. In the manufacture of such parts as leaf springs and wheel rims, however, grinding is employed because of the ease of application of the work to the grinding wheel and the resulting rapid removal of stock.

Instead of attempting to describe the grinding of a large variety of miscellaneous parts, a few of the more important operations will be dealt with. One or two of the standard makes of the various parts will be selected as typical, and the grinding operations used in their manufacture will be described. Where this description includes the make of grinding machine employed, it should be understood that other makes of machines of the same general type and capable of adaptation to the work could be used.

There are many types of ball bearings, but the interesting grinding operations are similar regardless of the type. In this article the grinding involved in the manufacture of the annular or radial type of bearing will be referred to specifically. The manufacture of steel balls for bearings is an art in itself. The mechanical equipment and problems are different from those in most manufacturing plants. On this account steel balls are frequently the only product manufactured by a concern. Typical grinding operations necessary in the manufacture of steel balls are described as follows:

Dry Grinding Operations on Steel Balls

The ball blanks, which are cold-headed for small sizes and hot-forged for large sizes, are subjected to a rough-grinding operation before they are heat-treated. This rough-grinding, which is done dry, removes a considerable part of the surplus metal, for the headed balls have a ring or fin around them left by the heading machine. As a result of this operation, each ball is brought to a much closer approximation of a truly spherical form than it is possible to obtain in the blank form made by either the cold-heading or hot-forging processes. Rough grinding also removes the decarbonized steel from the surfaces of the hot-forged blanks.

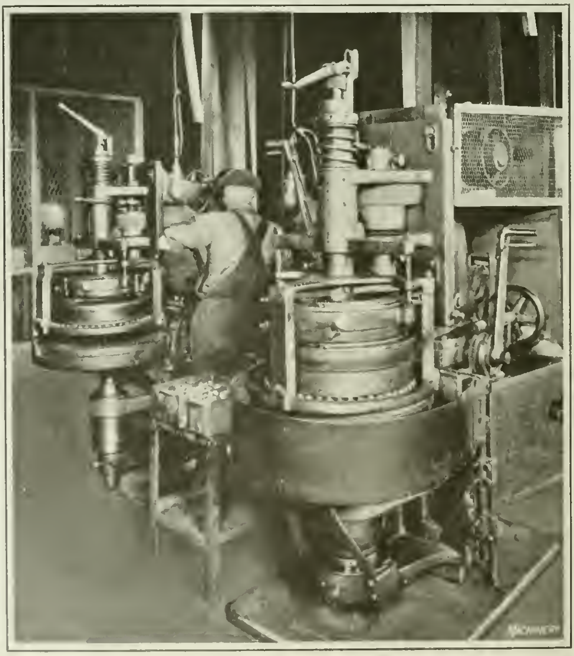


Fig. 1. Vertical Type of Machine used for rough-grinding Steel Balls for Bearings

The machines used for rough dry grinding are of the Grant type. A grinding wheel of the cylinder or ring type is mounted on a flat plate which is shown in the illustration Fig. 2. This plate, in turn, is mounted on the top of a vertical spindle, and rotates in the opposite direction to that of the driving or chaser ring *A* which presses down on the balls and keeps them in contact with the wheel. The inner and outer containing rings *B* and *C* are two concentric rings of different diameters, and are supported above the grinding wheel by springs. They are so beveled that the balls are held in a way that allows them to project slightly through the space between the beveled edges, and thus to be brought in contact with the grinding wheel.

The grinding wheel has a surface speed of about 5000 feet per minute, while the driving ring revolves in the opposite direction at about 60 revolutions per minute. The containing rings and grinding wheel are set eccentric to each other so that the balls, as they are rolled around the containing rings by the driving ring, travel across the top of the grinding wheel face. The side pull of the wheel on the ball constantly changes the axis upon which the ball rolls, and a new surface is constantly being presented to the grinding wheel. The result of the grinding is to produce a surface which is a close approximation to spherical form.

The grinding operation is not wholly automatic. The amount of pressure between the balls and wheel is controlled by a hand screw which raises the wheel-spindle. Only one ring of balls is ground at a time. The containing rings are filled with balls which are put in so that they touch each other, and while one charge of balls is being ground a second is being made ready. A gage indicates when the balls are ground to size.

After being rough-ground, the balls are heat-treated and hardened, then returned to the dry grinding department for the finish dry grinding operation. This operation is performed in the same manner and on the same type of machine as that employed in rough grinding, only a finer wheel is used, which removes the scale and brings the diameter a little closer to the desired finished size.

For rough dry grinding No. 40 grain wheels are used, while No. 60 grain wheels are used for finish dry grinding the large balls, and Nos. 90 or 100 grain wheels for grinding the small balls. The grade of wheel required is usually the hardest that it is possible to produce by the vitrified process. The point contact which exists between the wheel and the work results in a very high unit pressure, and this causes a severe dressing action, which softer wheels cannot withstand. Aluminous abrasive wheels are employed and they are operated at surface speeds ranging from 4500 to 5000 feet per minute.

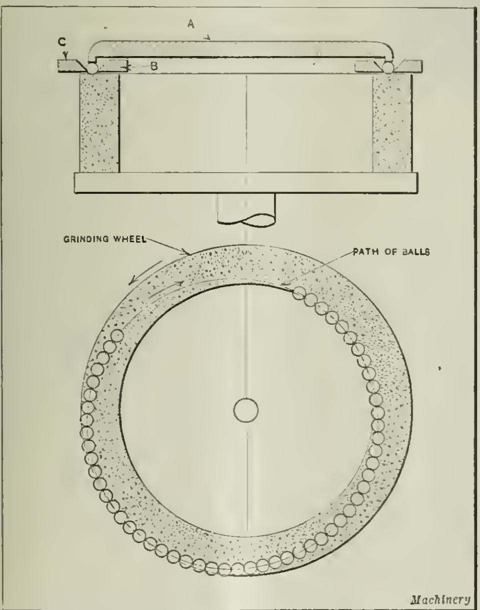

Fig. 2. Diagram showing Principle of Rough-grinding Operation

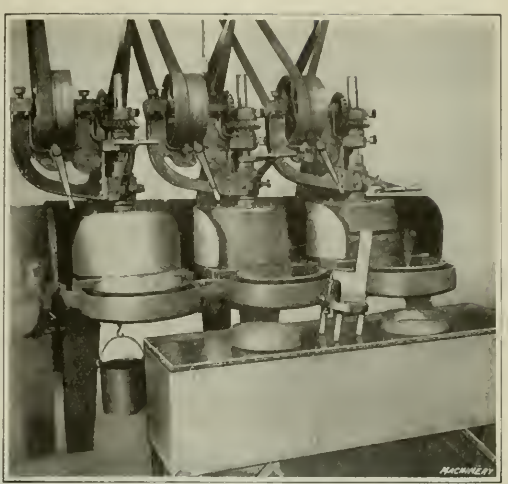

Fig. 3. Oil-grinding Machines, which are one Type used for finishing Steel Balls

The finish dry grinding leaves the balls in approximately spherical form, but with surfaces covered with small flat spots and scratches caused by the grinding wheel. There is still a considerable amount of excess metal on the balls, as they are about 0.010 inch over the finished size. The process of "oil-rolling" is for the purpose of removing the flat spots and scratches and bringing the balls down to nearly the proper size. The balls are tumbled in an iron barrel containing oil and No. 36 silicon carbide abrasive grain for from twenty to thirty hours, according to the amount of stock to be removed. The result of this operation is the production of practically perfect spheres, which are about 0.004 inch larger than the required finished dimension. This size is determined by selecting balls at random and measuring them with micrometer gages, the oil-rolling process being continued until they are 0.004 inch over the finished size.

Oil-grinding Steel Balls

The balls are reduced to the final size in oil-grinding machines (Fig. 3). The grinding part of these machines consists essentially of two iron rings, each of which contains an annular groove of such a size as to admit the balls. The balls roll in the groove of the lower of the two rings, which also contains oil and abrasive of the same kind as that used in the oil-rolling process, and are held by the upper ring. The upper ring is attached to a spindle and revolves the balls around in the groove containing the oil and abrasive. The grinding machines are provided with clock dials which, when the machines are started, are set to the approximate time when the grinding operation will be completed. Just previous to this time, balls are selected at random and measured for size. The time of grinding is usually from twenty to forty-five minutes, and the machine requires but little attention, except possibly to add more of the silicon carbide abrasive to the mixture.

Following the oil-grinding the balls are tumbled with hard wood sawdust, then with oil and Vienna lime, cleaned by being tumbled with hard wood sawdust again, and then tumbled with strips of kid leather, which completes the process.

Hoffman Process of Grinding Steel Balls

The final grinding operation on balls produced by the Atlas Ball Co. is performed on a Hoffman machine rather than on an oil-grinding or lapping machine, as it is claimed that more accurate results can be secured through this method. The oil-lapping machines are employed only on balls over ½ inch in diameter to remove some of the stock left for finish-grinding, these machines performing this operation more economically than has been possible on Hoffman machines because of the high grinding wheel cost with the latter. However, the difference in cost is not great, and, consequently, oil-lapping is omitted on balls less than ½ inch in diameter, and sometimes on the larger sizes.

The balls are produced from bar stock either by cold-heading, hot-forging, or hot-pressing, the process depending upon their size. Balls over ½ inch in diameter are next annealed, rough-ground, hardened and tempered, rough-ground once more, oil-ground or lapped, finish-ground, and polished. Balls less than ½ inch in diameter are ground before hardening on Hoffman machines after the first rough-grinding operation, then heat-treated and finish-ground on Hoffman machines.

Rough-grinding Operations Preceding Finishing Process on Hoffman Machine

The first and second rough-grinding operations are performed dry on vertical machines such as illustrated in Fig. 1, or horizontal machines of the type illustrated in Fig. 4. On the vertical machines the grinding wheel is located beneath the balls and is dropped to permit their removal at the completion of an operation. On the machine at the left, the grinding wheel is shown in the dropped position. These machines operate on the same principle as the Grant type of machines, the general arrangement illustrated in Fig. 2 being employed.

After a load of balls has been ground, the vertical lever at the rear of the machine on the right side is used to lower the grinding wheel. A tray attached to the left side of the machine is then swung into position above the grinding wheel. The lever at the top of the machine is next operated to lower the inner of the two rings forming the groove in which the balls rotate, and thus permit the balls to fall upon the tray. After the latter has been removed and the inner ring raised, both the outer and inner rings are dropped together a sufficient amount to permit unground balls to be poured between the driving and groove rings. When the machine has been loaded, the groove rings are raised to bring the balls in contact with the driving ring, after which the machine is ready for raising the grinding wheel into contact with the balls.

Grinding wheels of from 40 to 60 grain, according to the size of the balls, are employed for the first rough-grinding operation which lasts about eight minutes. In the second rough-grinding operation wheels of 60 to 90 grain are employed. An operation on ½-inch balls in which 0.005 inch of stock is removed, averages six minutes.

The horizontal machine illustrated in Fig. 4 is used for grinding balls from ½ to 2½ inches in diameter. It is supplied with a hopper when balls from ½ to 1 inch are being ground, but larger balls are fed by hand. The design of this machine is based upon the same principle as the vertical machines illustrated in Fig. 1. It consists essentially of a bed, a duplex wheel-head and two sliding work-heads. The wheel-head consists of a motor having a long armature shaft, both ends of which are provided with flanges for attaching ring grinding wheels. The wheel-head is stationary on the bed, the work-heads being adjusted to bring the balls into contact with the wheels by means of a large handwheel at each end of the bed. In this illustration the balls of one head can be seen projecting through the groove formed by the two stationary plates.

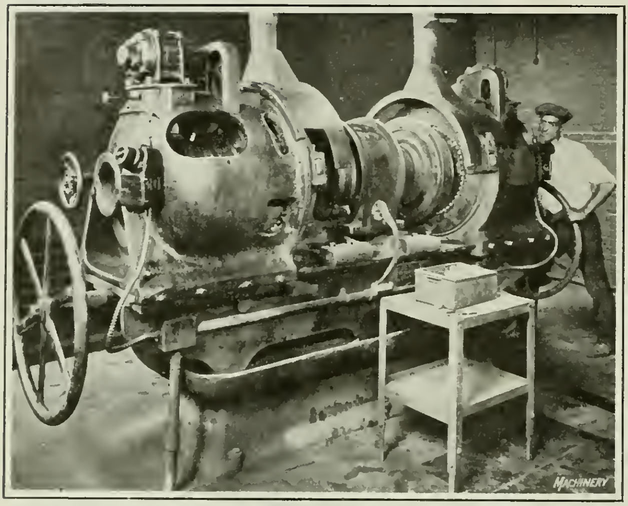

Fig. 4. Horizontal Type of Machine used for rough-grinding Balls varying from ½ to 2½ Inches in Diameter

Final Operation on the Hoffman Machine

The first Hoffman machine was designed to use abrasive grain for grinding. The balls were rotated between two grooved metal plates, together with a mixture of abrasive grain and oil covering the balls. Soft spots in the plates caused them to wear unevenly, making it necessary to repair or replace them frequently. The present Hoffman machine consists of a grinding wheel mounted on a horizontal spindle (Fig. 5). Opposite the grinding wheel is a stationary "rill plate," on the inner face of which (toward the grinding wheel) are a series of concentric annular grooves. The number and size of these grooves depend upon the size of the balls to be ground. In general the grooves are of such a depth as to admit one-third of the surface of the balls being ground.

The balls are fed into a runway which connects with the grooves in the plate, and under the action of the grinding wheel they rotate and roll around in the grooves until they have nearly completed one revolution, when they are thrown out into a trough and brought back into the runway to again pass through the grooves. The function of the trough is to mix the balls so that they will not be ground wholly in one groove, but each one will pass through all of the grooves, and in this way a more truly spherical ball will be produced. After the grinding wheel has been used for a time, grooves are worn in it corresponding to those in the metal plate. These grooves are allowed to become of practically the same depth as those in the metal plate, and are then maintained at this depth by dressing the surface of the wheel occasionally.

The grinding wheel is located close to the rill plate and revolves at slow speeds of from 30 to 60 revolutions per minute. At a certain point slots are cut through the rill plate through which fingers project to remove the balls from the grooves as the balls reach the fingers. When the balls leave the rill plate they are carried by gravity to a large magazine at the opposite end of the machine. A conveyor in this magazine carries the balls to a higher level from which they are once more returned by gravity through slots in the rill plate beneath the removing fingers and back into the grooves of this plate.

As a charge of balls is left for hours in one of these machines, each ball is carried many times through the different grooves of the rill plate. The illustration shows the balls in the trough which conveys them back into these grooves. Toward the end of an operation, balls from the charge are compared on a minimeter every ten minutes to ascertain whether they have reached the required diameter. A pressure of about 7000 pounds is maintained on the balls during the operation. This pressure is secured by means of a screw extending through the center of the wheel-spindle and the magazine to the right end of the machine where a handwheel is located for tightening or loosening the screw against a heavy spring. By locating the screw as mentioned, a uniform pressure is placed on all balls in contact with the wheel. There is no slipping or twisting of the balls because of this pressure.

The grinding wheel has an outside diameter of 24 inches, a hole 12 inches in diameter, and is 4 inches thick. As many grooves are cut in a rill plate as can be spaced across the ring wheel between its hole and periphery. The number of grooves ranges from two to twenty-eight, according to the size of the balls for which the plate is intended. The magazine permits the machine to be loaded with charges of balls averaging 240 pounds. With a charge of ½-inch balls, approximately 1½ hours are required to remove 0.001 inch of stock. Kerosene is used as a coolant, because it has been found that with this oil all sliminess on the balls is eliminated and that the abrasive particles loosen completely from the balls and are carried away by the kerosene. The abrasive particles also settle readily to the bottom of the filtration tanks.

The finished product of the Hoffman machine is of much better quality than can be produced by finish-grinding on other types of machines. The production is, however, much lower; furthermore, it is impossible to grind in this machine the rough ball blanks as they come from the forging or heading machine. Very fine, hard wheels are used on the Hoffman machine, the grain size being generally XF and the grade as hard as it is possible to make by the vitrified process.

Grinding Outer Rings of Ball Bearings

The outer soft steel rings of ball bearings are turned products, usually made on screw machines. The groove is roughed out and the ring is then ready for its first grinding operation. This consists in surfacing the sides of the ring on a surface grinding machine of the vertical-spindle type, such as the Blanchard, shown in Fig. 6, or Pratt & Whitney, or by the use of special machines which have been designed by manufacturers of bearings for this particular class of work. These special machines are similar to the Gardner or to the Besly double-head machine. The bearing is held in a special fixture and rough-ground to the proper thickness by the use of two wheels, one grinding on each side.

After being surface ground, the rings are hardened and finish surface ground on the same type of machine as that used in the first grinding operation, but with different grinding wheels. The rings are then mounted in gangs on arbors and ground cylindrically on ordinary plain cylindrical grinding machines (Fig. 7). In some cases, the rings are roughed on one machine and finished on another, but in other plants the operations are combined. The ordinary wheels used for cylindrically grinding hardened steel are generally used for this work, although the finish required may be better than the ordinary commercial finish. The requirements as to finish may make it necessary to use a No. 60 grain wheel in place of the more common No. 46 and 24 combination wheels. No. 36 combination grain wheels are also employed.

Grinding Grooves in Outer Rings

The grooves in outer ball-bearing rings are next rough-ground on special machines of the oscillating work-head type. The Van Norman automatic radial raceway grinding machine is shown in Fig. 8 grinding a large outer ring. After this machine has been set up and the work placed in the work-holder, the wheel is brought in contact with the raceway, after which the groove-grinding operation is entirely automatic. It is possible for one man to operate several of these machines.

For the groove grinding of outer rings, two wheels should be used—one for roughing and another for finishing. Vitrified wheels made up of grain No. 46 or 60 should be used for roughing, while for finishing, elastic wheels of about grain No. 80 give the best results. Elastic wheels are almost always used for finishing, but they are too expensive compared with vitrified wheels to be used for the removal of the large amount of stock necessary in the roughing operation. An excellent finish is produced by the elastic wheel when only a few thousandths of an inch of stock is removed. Groove-grinding should be done wet and the wheels trued and dressed with a diamond.

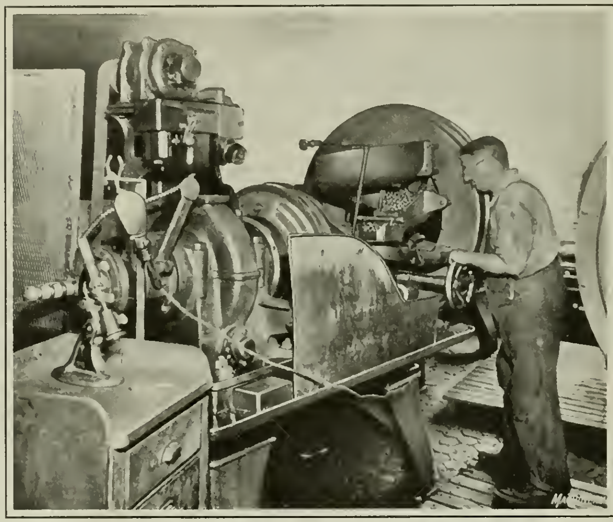

Fig. 5. Hoffman Machine which is used for finish-grinding Balls after the Roughing Operation

Grinding Inner Rings of Ball Bearings

Rough and finish surface grinding is done in exactly the same way as the corresponding operations on the outer rings, and the same types of machines are used.

The next operation on inner rings of ball bearings is that of bore grinding, which is an ordinary internal grinding operation, and may be performed on any standard internal grinding machine. A good finish is required, and this is secured by using wheels of No. 46, 50, or 60 grain.

The groove grinding can be done on the oscillating-head machine or on a small cylindrical grinding machine. The wheel face is formed with a diamond, and when a plain cylindrical machine is used the wheel is fed straight into the groove in the ring. With this type of machine, wheels of No. 46 grain are used for roughing and No. 80 or 100 grain for finishing. Generally both the roughing and finishing wheels are made by the vitrified process, although elastic wheels are sometimes used.

Great care must be exercised in grinding ball race grooves. Not only must the grooves be very accurately sized, but the

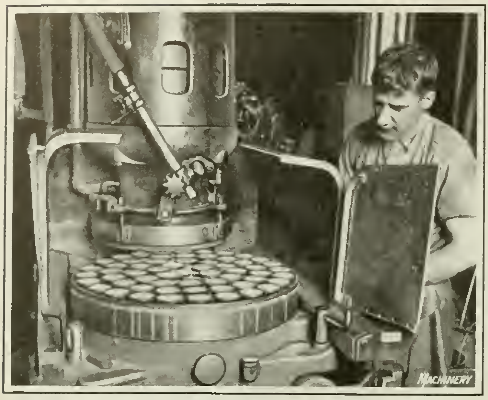

Fig. 6. Vertical-spindle Grinding Machine surface-grinding the Sides of Ball-bearing Rings

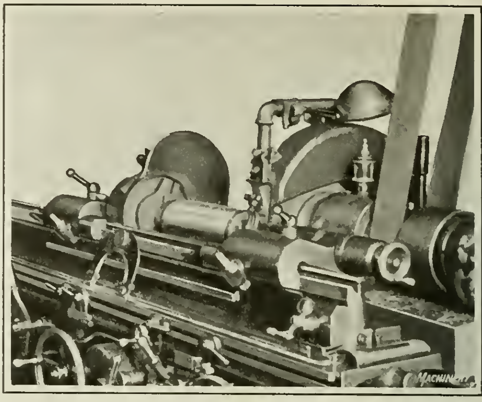

Fig. 7. Cylindrical Grinding Operation on the Outside of a Gang of Ball-bearing Rings

finish must be the best it is possible to obtain on a commercial basis. The life of a ball bearing depends as much on the character of the raceway as on the balls. The grinding must not overheat the surface of the raceway, on account of the resulting tendency to "skin soften" or produce minute cracks and checks in the surface, which would cause the bearing to fail after short service.

A Van Norman machine is shown in Fig. 9 grinding a double-row end-thrust ball-bearing plate. This plate is 14½ inches in diameter, and each groove is intended for balls two inches in diameter. The radial type of machine can also be applied to certain other classes of work in the automotive field. Two examples are shown in Figs. 10 and 11. The operation illustrated in Fig. 10 is that of grinding the outer radius on an automobile universal joint cover, and Fig. 11 shows a machine grinding the ball end of a steering knuckle.

Grinding Roller Bearing Cups

Grinding operations are employed in the making of three important parts of one type of roller bearing, namely, the cup, the cone and the rollers (Fig. 12). The cups, after being hardened and inspected, come to the first grinding operation about 0.008 inch over size. Approximately this amount of stock is left on all surfaces which are ground. The edge of the cup on the side having the opening of smaller diameter is first surface ground. This may be done on a machine of the universal type. The headstock is set at 90 degrees, and the piece is held on a magnetic chuck (the face of which is in a vertical plane) and the edge is ground on the face of a straight wheel, the operation being similar to surface grinding on a rotary surface grinding machine. This ground surface is then used as a reference surface during the next grinding operation. A Norton multi-purpose machine could be employed for this operation. A machine. such as the Heald automatic piston-ring grinder is also adapted for grinding the side or edges of bearing races, especially when the grinding is done on a large scale.

The next operation consists of grinding the taper bore, which constitutes the outer raceway of the bearing. A universal grinding machine is used, the work-head being swiveled to give the proper taper and a magnetic chuck for holding the work. A ring of non-magnetic material on the chuck is used to center the work. The taper bore is ground dry, this being the only dry grinding operation on the cup, and this ground surface is used as the reference surface for the grinding of the outside diameter.

The outer surfaces of roller bearing cups are finished by grinding on any plain cylindrical machine like the Norton type. A number of the cups are mounted on a special mandrel equipped with double tapered collars, each collar carrying two of the cups that are to be ground. The cups are placed on the mandrel with the tapers extending in opposite directions, and are held securely by being clamped between

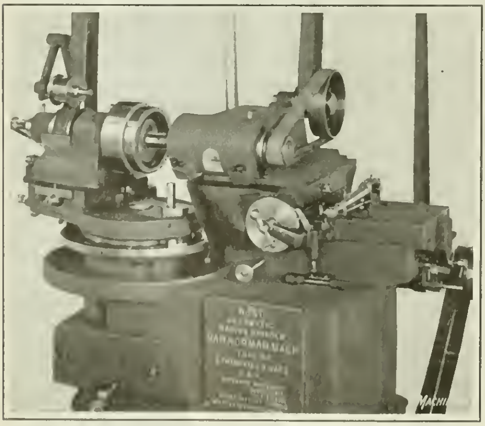

Fig. 8. Grinding the Raceway in an Outer Ring using an Automatic Radius Grinder

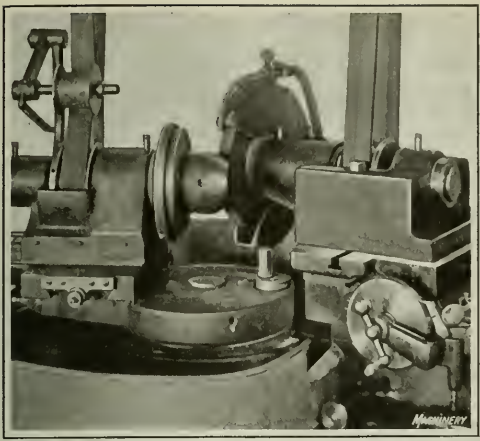

Fig. 10. Grinding the Outer Radius on a Universal Joint Cover

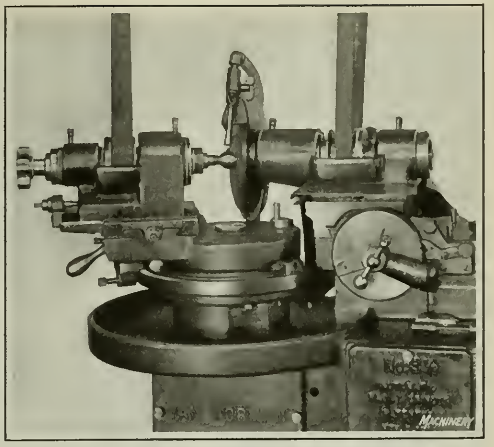

Fig. 11. Grinding the Ball End of a Steering Knuckle

a flange at one end and a ring at the other. While one "gang" of cups is being ground, another mandrel is being loaded.

Grinding Cone or Inner Raceway

The edge at the large end of the taper on the cone is ground first and used as a locating surface. The grinding is done wet on the same type of machine that is used for the first grinding operation on the cup.

Grinding the bore of the cone is a simple internal grinding operation performed on any well-constructed internal grinding machine. The bore is then used for locating the work on a mandrel while the tapered raceway is being ground. This is ground on a universal machine using an expanding mandrel to carry the cone. The work-head of the grinding machine is set at the desired angle and the grinding is done on the face of a straight wheel.

The last grinding operation on the cone is very important. The two shoulders *A* and *B* in Fig. 12 must be ground exactly parallel with each other and at the proper angle with the bearing surface, in order that the bearing may sustain a thrust load satisfactorily. The method by which this grinding operation is accomplished is to equip a universal grinding machine with two wheels of different diameters, and have the work-spindle of the machine set at an angle so that the two wheels may come in contact with the work simultaneously and grind the two shoulders. To facilitate the truing of the wheel, two diamonds are mounted in a holder secured to the work-spindle housing.

Grinding the Rollers

The only grinding operation on the rollers is that of grinding the bearing surface. This may be done on a Brown & Sharpe grinding machine equipped with a special magazine feed mechanism. The rollers are put in a feed chute, which brings them to a position to the right and in front of the grinding wheel face. A push-rod pushes an individual roller between two spring fingers, which then carry it forward to a position between the machine centers where it is automatically gripped and held in the proper position for grinding.

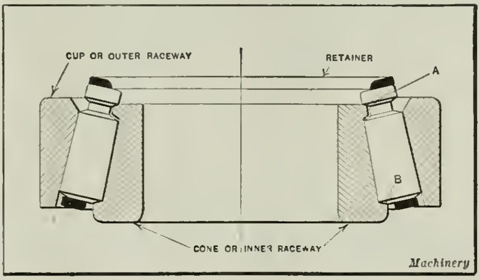

Fig. 12. One Type of Roller Bearing

After the roller is ground on the face of a straight wheel the tail center is withdrawn and the roller drops into a receiver. The tail center is then allowed to spring back into place, and as it does, it comes in contact with a new roller held in place by the spring fingers. This operation is entirely automatic except that it is necessary to feed the wheel in at intervals to compensate for wheel wear.

Another type of roller bearing contains only straight cylindrical parts. The grinding operations, although an important part of the manufacture, do not involve special features, as they are simply straight cylindrical and internal grinding processes performed in the same manner and with the same machines as work of a similar nature. Accuracy of grinding is essential.

* * *

THE SCARCITY OF PLATINUM

Platinum is used to a considerable extent in the industries, but the great advance in the price of this metal during recent year has had a retarding influence upon its industrial applications. The advance in price was due primarily to the use of platinum in the manufacture of war materials and to the scarcity of the metal, most of which in former years had come from Russia. As soon as the price increased, due to its scarcity, the metal was immediately diverted to a use for which it is really not adapted, namely, jewelry. There is no reason to doubt that the practice of setting precious stones in platinum has been adopted because of the high cost of the material. In 1920, 57 per cent of the platinum consumption of the United States was used in the jewelry trades, 19 per cent by the electrical industries, and 10 per cent by chemical works, while the remainder was distributed between dental uses and minor industries. While substitutes for many of the uses of platinum in the electrical industry have been found, it still plays an important part in this field. If through increased supply the price of platinum should again fall below that of gold, it is likely that it would cease to be used for jewelry, in which case the supply for industrial purposes would be all the greater.

Methods Employed in Making Radio Head-phones at the Plant of the Newark Engineering & Tool Co., Newark, N. J.

THE purpose of head telephone receivers is to change the varying direct-current impulses of the receiving circuit to sound waves, and the principles of construction are the same as in ordinary telephone receivers. More care is required, however, in building a radio receiver than for the ordinary telephone.

The construction of the head-phone receiver will be understood by reference to Fig. 1. The parts are assembled into an aluminum case, and are covered by the diaphragm which is enclosed by a hard rubber cap. The most vital unit is the magnetic coil, of which there are two in each instrument. These coils are wound on insulated iron cores, such as shown at *A*. After winding, the coils have the appearance shown at *B*, the lower one of which is insulated, while the upper is not. The two coils are connected; the ends of the wires are attached to two brass screws located in a fiber terminal piece *C*. The arrangement is shown in the view of the assembled instrument.

The terminal piece is fastened into the case and contains two radial holes for plugging in the connection to the radio receiving apparatus. An electromagnetic force is set up whenever a coil of wire is wound around a soft iron core, so that in a receiver coil any variation in strength of the electrical impulses correspondingly affects the movement of the diaphragm. Consequently, louder or fainter tones are received according to the excitation in the magnetic coils. In addition to the magnetic force induced by the winding of the coils there are two permanent magnets *D* fastened into the case which cause an additional bellows movement of the diaphragm and serve to balance its action. The instruments are hung in a yoke *E* so that they are free to swivel and adjust themselves to the head. The end of the yoke stem has a suitable connection to the head band, the parts of this connection being shown at each side of the yoke.

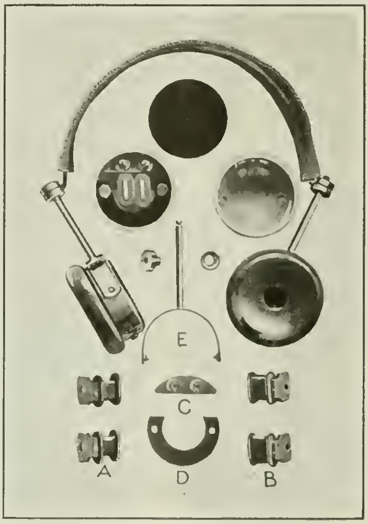

Fig. 1. Head-phones and Parts

Drawing and Threading the Case

In dealing with the manufacture of this instrument, as carried on by the Newark Engineering & Tool Co., Newark, N. J., only certain operations will be referred to. Attention will be focussed mainly on the making of the coils and the magnets. The aluminum cup which forms the case is made of sheet alumium, 0.080 inch thick, and is drawn in two operations, the second of which is performed with the set-up illustrated in Fig. 2. The machine used is a double-action back-geared Bliss press, and the dies are of the push-through type. A shell produced in the first operation is shown in the die; it is held in place by the punch-holder while the punch passes through it and completes the shell.

After the holes have been punched in the cases, they are ready to be threaded for the hard rubber cap. The thread is produced by rolling, as illustrated in Fig. 3. Here a Rockford tool-room lathe is shown equipped with a thread-rolling tool and a chuck having two pins that engage the punched holes in the cases to drive them. The cases are supported at the end during the threading operation by a fiber collar which has a female center to receive the regular lathe center. There are twenty threads per inch rolled on the case, and the tools are kept clean by the frequent application of kerosene. The open ends of the cases are next shaved to length; this is also done on a Rockford lathe. The parts are finally polished, properly stamped, and delivered to the assembling department where they are assembled and packed for shipment.

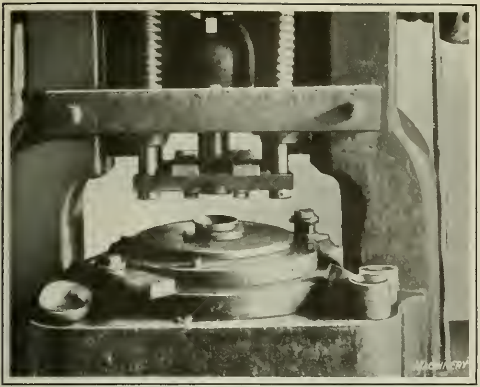

Fig. 2. Second Drawing Operation on the Aluminum Cases

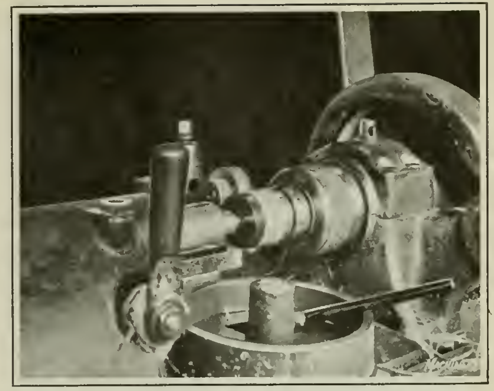

Fig. 3. Rolling the Threads on the Cases

Making the Magnetic Coils

The coils are the most important part of the telephone receiver, and careful workmanship is necessary in every phase of their manufacture. The cores are made from Norwegian iron, and are punched out and bent to a right angle, as shown at *A*, Fig. 1, on a power press. They are then fitted with fiber flanges, which are pressed on by means of a foot-press, the punch of which is slotted to pass over the end of the core. The operation of assembling the lower flange is illustrated in Fig. 5, which also shows a number of the fiber flanges and a box of iron cores to which the flanges are to be assembled. This operation is very simple, and is identical to that of assembling the upper flange. The section between the flanges is protected by insulating paper manufactured by the Irvington Varnish & Insulator Co., which is stuck on with shellac. After the coil has been wound it is also protected by insulating cloth, brushed with shellac.

Fig. 4 is a view showing one section of the winding department of the Newark Engineering & Tool Co. in which a number of special winding machines are employed to wind the coils. These machines were especially designed and constructed by George J. Zisch, president and general manager of this company, who is responsible for the designing and the manufacturing methods used in manufacturing the head-set.

The winding machines are driven by 1/50-horsepower induction motors which have proved the most efficient installation. The spindle which carries the core also drives a speedometer so that the exact number of turns may be obtained. No. 40 gage enameled magnetic wire is used, each core or spool containing approximately 4000 turns or about one-quarter mile of wire. It will be noted that these coils are placed in boxes on the bench. They are reconnected in pairs by a slightly coarser wire which furnishes the leads to the terminal connections of the instrument. Insulating the coils after winding completes their manufacture, and they are then sent to the assembling room.

Fig. 4. Section of the Coil Winding Department

Other Operations of Importance

The permanent magnets used in this telephone receiver are made of tungsten electric magnet steel, which is a very tough material; consequently, it has been found advantageous to punch out each magnet individually. The practice in this shop is first to cut out slabbed blanks from strip stock, 3/32 inch thick and 1½ inches wide, and next punch the two holes by means of which the magnets are fastened into the case. The final power press operation is punching out the center. The press work is performed on Zeh & Hahnemann single-action presses, the set-up for the final operation being shown in Fig. 6. The film of oil on the work makes it necessary to use a thin-edged pinch-bar to remove the work from the face of the die, but the dies themselves are of simple construction and need no special description. A quantity of finished magnet stampings is shown on the bolster plate of the press.

The hardening of the magnets preparatory to magnetizing is a very delicate operation, and great care must be taken not to apply too much heat; otherwise the steel cannot be properly magnetized. In magnetizing, which is the final operation, the magnetic plates are charged with a direct current of 110 volts, 12 amperes. The fiber terminal piece *C*, illustrated in Fig. 1, is punched from sheet stock, drilled and tapped for brass inserts which are pressed in place to accommodate the terminal screws for the magnetic coils.

Needless to say, all parts used in the construction of an

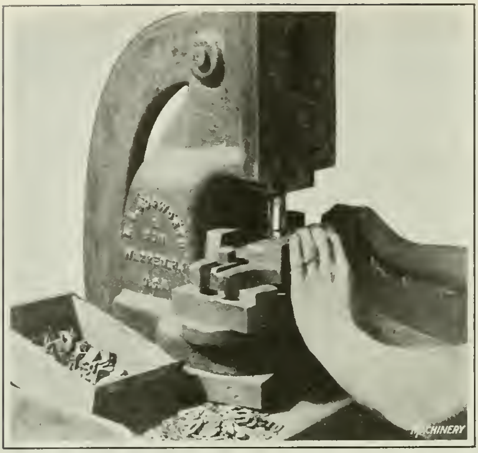

Fig. 5. Assembling the Fiber Flanges, using a Foot Press

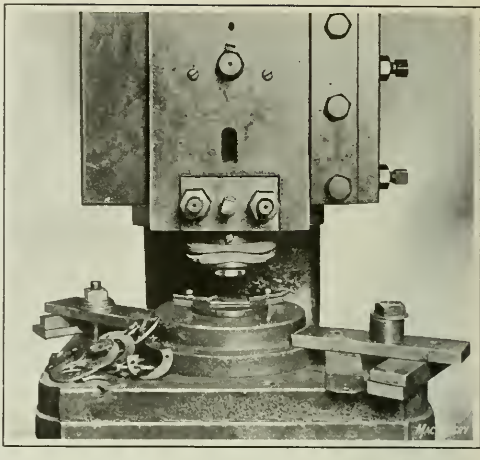

Fig 6. Press for punching out Centers of Permanent Magnets

instrnment of this kind are carefully inspected before assembling, and the assembled product is given a final and searching inspection. Coil terminals are brazed to the terminal screws and the lead wires from the coils are insulated with tubing. The permanent magnets are fastened into the bottom of the case and care is exercised to prevent them from touching the magnetic coils. The assembled instruments are then tested for sound, each head-phone being connected to a tuning coil so that both phones of a set will be closely paired for sound.

WINDING SMALL HELICAL SPRINGS

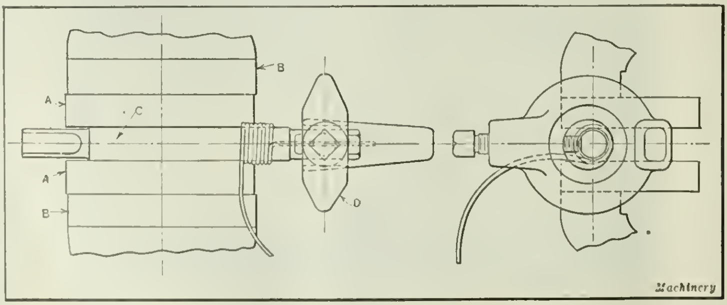
By A. A. FORSTER

The accompanying illustration shows a method of winding small helical springs which requires no equipment other than an ordinary bench vise, a suitable mandrel, a lathe dog, and two pieces of hard wood. The writer has found this method practical for making compression, tension, or twist helical springs from piano wire as large as No. 30 gage. In proceeding to wind a spring, the two hard wood blocks *A* are placed between vise jaws *B* as shown. The width of blocks *A* should be such that they will rest on the vise slide and come flush with the top of the jaws.

The bar or mandrel *C* must be selected to suit the size of spring required. A lathe dog *D* or a clamp is used to hold the spring wire to the end of the mandrel. To start winding after the wire has been clamped to the mandrel, first bend the wire so that it will be at an angle of 90 degrees with the mandrel at a point about ¾ inch from the lathe dog. With the spring wire held in the left hand in a vertical position and the lathe dog or clamp held so that the bend just made rests in a horizontal plane, the vise is closed so that the wire is forced into the wood.

The winding is now accomplished by turning the clamp or lathe dog, allowing the wire to follow the original indentation made in the wood. In winding tension and twist springs, the mandrel should be held nearly horizontal or parallel with the tops of the wood blocks, but to wind a compression spring the bar or mandrel should be held at an angle as determined by the pitch of the spring required.

The approximate diameter of a mandrel required to give a certain diameter spring, using a wire of known gage, can be determined by referring to MACHINERY'S HANDBOOK, page 443. If tables are not available some idea of the size of mandrel required may be gained from the fact that in winding a spring from No. 36 gage wire it was found necessary to use a steel bar or mandrel about ½ inch smaller in diameter to obtain a spring having an outside diameter of ¾ inch. For smaller springs the mandrel must be proportionately smaller to obtain the required outside diameter.



Method of winding Small Helical Springs in a Vise

GLASS-TOPPED DRAWING TABLE

By FRANK H. JONES

A handy table to have in any drafting-room can easily be made from an old, worn-out drawing-board placed on horses and covered all over with white paper. Around the two sides and back of the table thus covered, build up an enclosure by placing pieces of 2- by 4-inch planed stock, the 4-inch side upright, along the edges. Over the top place a piece of heavy glass which will cover the entire surface of the built-up area. This gives a plane glass surface covering a well four inches deep which is open on the front side.

A portable electric light cord with a hand lamp completes the outfit. The lamp cord should be long enough to allow the lamp to be moved anywhere under the glass. Such a table, once constructed, will be found indispensable in checking drawings and tracings. The part of the glass not in use should be kept covered with heavy paper or some dark material.

STANDARDIZATION OF TOLERANCES

While tolerances and allowances for machine parts must be related to the function of each part, it is of course practicable to standardize such data in so far as it applies to certain general classes of machine fits. This fact was emphasized in an editorial published in July, 1919, MACHINERY, page 1033, in which a reasonable degree of standardization for tolerances and allowances was advocated, the plan being to base the standards upon data which experience had proved to be satisfactory for different general classes of service.

Important work in connection with standardizing tolerances and allowances for machine fits is now being done by a sectional committee of the American Society of Mechanical Engineers. This "Committee on Plain Limit Gages for General Engineering Work" has as its chairman, Col. E. C. Peck, general superintendent of the Cleveland Twist Drill Co. At a meeting held July 17, the work previously done was discussed by the committee and certain changes suggested, the aim being to finally recommend standards for adoption by the society which will be based upon approved practice and which will be of considerable value to the machine-building industry in general.

These standards include eight classes of machine fits designated as: (1) loose fits; (2) free fits; (3) medium fits; (4) snug fits; (5) wringing fits; (6) tight fits; (7) medium force fits; (8) heavy force or shrink fits.

The loose fits allow considerable freedom and are intended for agricultural and mining machinery, controlling apparatus for marine works, textile, rubber, candy and bread machinery and general machinery of a similar grade, as well as some ordnance material.

The free fits provide for a liberal allowance and are for running fits with speeds of 600 revolutions per minute or over, and journal pressures of 600 pounds per square inch or over. Examples under this classification include certain parts of generators and engines, many machine tool parts and some automotive parts.

The medium fits are based upon a medium allowance and are for running fits under 600 revolutions per minute and with less than 600 pounds per square inch journal pressure. This class also includes sliding fits and the more accurate machine tool and automotive parts.

The snug fits have a small allowance and represent the closest fit which can be assembled by hand, requiring work of considerable precision. This class is used where no perceptible shake is permissible and where moving parts are not intended to move freely under load.

The wringing fits represent practically metal-to-metal contact, and the assembling is usually selective and not interchangeable.

The tight fits have a slight negative allowance and are more or less permanently set, light pressure being required to assemble. Examples include fixed ends of studs for gears, pulleys, rocker arms, etc., driving fits in thin sections or extremely long fits in other sections. This class is applied in automotive and ordnance work as well as in general machine manufacture. It may be used for shrinkage fits when the sections are very light.

The medium force fits require considerable pressure and are for permanent assembling. Applications include locomotive wheels, car wheels, armatures and the assembling of crank disks on their axles or shafts. This class also applies to shrinkage fits for medium sections or long fits.

The heavy force and shrinkage fits have considerable negative allowance and are applied where the metal will withstand considerable stress and where a heavy force fit is impracticable. Examples include locomotive tires and heavy crank disks of large engines.

THE BELGIAN MACHINE TOOL MARKET

Industrial conditions in Belgium are improved. There is no longer an immediate threat of German competition. Notwithstanding these favorable aspects, the Belgian market for American machine tools is not promising, because there is considerable American machinery in stock, probably aggregating 15,000,000 francs in value. It will no doubt require another year for the sale of these machines, even at the sacrifice prices at which they are being offered. Acting Commercial Attache S. H. Cross, of Brussels, states that American-made machine tools stand high in favor even at the prevailing higher prices. At the recent Commercial Fair this fact was shown to be true—one of the best known Belgian manufacturers is said to have sold no lathes whatever, while there were several purchases of American machine tools. Some universal milling machines as well as broaching and balancing machines were ordered from American manufacturers, which is an indication that the American prices are not prohibitive. The Belgian machine dealers, however, after having suffered considerable losses, cannot be expected to stock machinery again for some time to come.

German Competition in the Belgian Market

In view of constantly-increasing labor costs in Germany, the German manufacturer cannot produce a machine tool to order and deliver it in Belgium at a price much below the quotations of American machine tool builders. On the other hand, German machinery dealers who accumulated considerable machinery stocks before production costs in Germany had risen greatly, can still undersell American tools as long as such accumulated stocks hold out. A case of this kind is noted in which a well-known American radial drilling machine is quoted in Belgium at 13,500 francs, while a German machine, apparently a reproduction of the American tool, could be purchased in Germany a few months ago for 4000 francs. It is probable that at present this German machine at the factory would cost double this amount.

The position of the German manufacturer is exemplified by another instance: An American representative quoted a Belgian prospect 82,000 francs for a well-known make of American motor-driven lathe, with motor. The representative was told by this prospective customer that he could practically duplicate the machine for 40,000 francs by buying a German machine. The customer delayed placing the order in Germany; when he finally did so he was informed that the price had been advanced to 80,000 francs, without motor.

Future Outlook Encouraging

The outlook for American machine tool sales in Belgium appears, on the whole, to be more hopeful than it has been recently. Better results can probably be obtained in this market by supporting local representatives to the extent of supplying moderate stocks on consignment. The recent losses of the average Belgian firm have been too great to permit any purchases for stock. Orders for machinery for restoration purposes naturally have been concluded; however, some shop construction is reported in the vicinity of Brussels, and a certain amount of buying for replacement and development is being done. It is quite likely that moderate price reductions would somewhat increase the sale of American shop equipment in Belgium.

Efforts have been made recently to place agencies for small American electrically-driven woodworking machinery in Belgium. In view of the low wage rate of hand-labor and the small size and limited means of most Belgian woodworking shops, it is believed that the market for this equipment is very limited and would hardly compensate the cost of advertising necessary to place these products before the prospective customer.

THE TREND OF MACHINE TOOL PRICES

During the last eighteen months machine tool prices have tended steadily downward, but there are signs which indicate that the low level has been reached and that from now on the trend will be upward. A few machine tool builders have already increased their prices in view of the conditions in the material and labor markets, and others are contemplating a readjustment in prices within a few months.

When prices were reduced to the present level, materials had come down to a point from which they have since considerably risen; also there was a general belief that wages would come down to a much lower level than they have, and on the strength of this, manufacturers reduced their prices below replacement costs. Now, with an increasing demand, it becomes necessary to replenish the stocks at costs higher than were anticipated. Pig iron, castings, and steel are higher than at the beginning of the year. The hourly rates for labor have not been materially reduced, and with the scarcity of skilled mechanics in the machine-tool building field, there is no reason to expect lower labor costs.

Doubtless the expectation of increased machine tool prices is the reason why many large corporations have placed substantial orders during the past two months. They realize that the present is the best time to buy not only because prices are at their lowest but because deliveries are prompt. Unmistakable indications of rising prices usually result in a rush of orders which in turn slows down deliveries.

* * *

TRADE ASSOCIATION ACTIVITIES

The activities of a number of associations, most of them in the building trades, formed for the purpose of maintaining prices of material and labor at fictitious levels, have created in the minds of many people the erroneous belief that trade associations as such are harmful to the public welfare. Secretary Hoover has stated, and investigations have shown, that not one-tenth of the many hundreds of manufacturers associations in the United States have engaged in any activities that could be construed as an infringement of the law. Trade associations may and should engage in many activities that are of benefit to the public interest as well as to their own members; because by decreasing the costs and hazards of conducting business, prices usually are reduced. Many such associations are actually working toward a reduction of prices to the public. Secretary Hoover is particularly emphatic in his statements that trade associations as a whole are useful, and that violations of the law by a few associations does not condemn the lawful and useful activities of the others.

Among the many useful activities in which trade associations may and should engage, are the adoption of standard forms of contracts; collection of credit information; standardization of machinery and processes; adoption of uniform trade practices and methods; promotion of the education of apprentices; employes' welfare work; cooperation to oppose unfair legislation; promotion of closer relations with the Department of Commerce; collection of statistics of production, costs, consumption, and distribution; and the publication of such statistics for the benefit of their members and the public.

Some of the activities in which trade associations may not engage are agreements to increase or maintain prices, and to curtail production or suppress competition. Neither may they adopt any marks or labels which would tend to result in the same price being charged for articles made by different manufacturers bearing identical labels. The collection of credit information is permissible; provided it is not for the purpose of establishing black-lists.

As practically every manufacturer, in whatever line engaged, is now a member of one or more trade associations, manufacturers generally are interested in knowing what trade association activities are legal and are encouraged by the Government, and what are not permitted.

UTILIZE YOUR SPARE TIME NOW

While manufacturers are taking advantage of the industrial depression to improve their plants, working men should prepare for increased activity. Many thousands of workers have more spare time than they know what to do with, and those who give thought to their future will devote this time to practical study of the work they wish to engage in so that when the door of opportunity opens they will be ready and qualified to enter. It is not necessary to attend school to accomplish this. There is an abundance of literature available on all phases of shop practice, and each man can be his own instructor.

Now is the time for every working man to take stock of his knowledge and to see what lack may bar his future progress. He should ask himself, "Do I know all there is to know about my job?" "Do I know what feeds and speeds should be used on different classes of work?" "Do I know what lubricants to use for different materials?" "Do I know what factors govern production and whether this design of die or jig is the most efficient for this particular work?" The answers to all these questions and many others are available in the technical literature of today and men can obtain the books needed with little expenditure. Even if that is not feasible for a man out of employment, he can always resort to the public library. The important objective is to form the habit of reading and studying, now that there is time.

BALL BEARINGS FOR TEXTILE MACHINERY

There are many opportunities for the economical use of ball bearings in textile machinery, and in several textile mills they have been provided to replace the plain bearings furnished by the builders of the machinery. In one instance several hundred ball bearings were so installed by one of the leading textile manufacturers.

The users of textile machinery would be better served if these bearings were made part of the original equipment by the manufacturer. Ball bearings are of as great value in textile machinery as in any other line of industrial equipment which requires bearings, and their use would often avert bearing trouble while effecting a considerable saving in power.

Textile machinery has been developed to a high state of efficiency by following the somewhat conservative principles of old-time mechanics; but some of the modern developments in machine construction could now be applied advantageously.

Cutting Prices Below Cost

By A. W. HENN, President, National Acme Co., Cleveland, Ohio

IN a period of depression such as we have just passed through and out of which we are now emerging, reductions in prices are naturally the order of the day, partly because labor and material costs in such times are generally reduced to a considerable extent, and partly because the law of supply and demand forces prices down. At first there is an attempt to keep prices at a level where a fair profit may still be realized, but after a while competition generally forces them down to a level where there are not only no profits but where goods are actually sold below cost.

At first sight it may seem uneconomical and unwise to sell the products of industry below cost at any time but there are reasons why it may be advisable to do so under certain circumstances; and there is generally a period during every depression when the need for selling below cost arises. The demand may be so small and competition so keen that if one or more manufacturers in a given field refused to accept conditions as they are, they would get scarcely any share whatever of the small business that is to be had. This, in turn, would make it necessary for them either to close their factories entirely and permit their organizations to go to pieces, or to carry a certain part of the plants along working on stock; this is not only expensive for the time being but sometimes may be followed by losses as great as would be the selling of the product immediately at a price lower than its actual cost.

During the present depression many manufacturers have concluded that it would be better for them to maintain their organizations as nearly intact as possible, even though this could be done only by selling at a loss. This has also made it impossible to hire more men, at least on a part-time basis, and to prevent too serious effects from unemployment.

Need for Selling below Cost is now Past

That period of the depression when it was necessary to accept practically whatever price the market would bring has now passed, and it is time to stop the practice of selling without regard to production costs. The demand in almost every line of metal products is now sufficient to warrant increases in prices to a level commensurate with costs, and manufacturers in general ought to recognize this fact. A prolonged period of selling below cost after the most acute stage of the depression has passed is injurious not only to the individual manufacturer but to the industry as a whole, because it deters the return to normal economic and industrial conditions. The shop or industry that continues to sell below cost naturally forces its competitors to follow a somewhat similar procedure, and as long as any industry disposes of its products thus, its economic condition is such that it cannot itself be in the market for the products of other industries, except to the extent of the bare materials that are used in production. On the other hand, as prices return to normal, and fair returns are realized on capital investment, the manufacturers themselves come into the market for new and improved equipment, thus aiding the early revival of industrial conditions in the entire field.

The demand at the present time for practically all of the products of the metal-working industries is brisk enough so that prices must rise. In some industries this increase in prices has already taken place, while in other branches it has yet to come; but in every case it is safe to say that the low level either has been reached and passed, or it has been reached and will soon be passed. Business is coming back much faster than one might have expected a few months ago, and unless some deterring influences are again brought into action—like nation-wide strikes that affect the supply of raw materials or transportation—there is every reason to believe that steady improvement is ahead, and that the return to normal conditions is assured. In some branches of the industry it may take somewhat longer to come back to normal than it will in others. The automobile industry may be said to have returned to a normal state already, and so have the industries depending upon it, such as the alloy-steel and the parts manufacturing lines.

Future Prices must be Higher than the Pre-war Level

Prices in finding a level which will cover costs and leave a satisfactory return on capital investment, must today unquestionably be a certain percentage higher than pre-war prices in every line of manufactured goods, because wages are definitely on a higher plane; and there is no reason to expect that wages will soon return to the pre-war level. Broadly considered, there is no reason why business should not be as stable and normal with a higher wage level and correspondingly higher prices as it was previous to the war. The only thing that is required is such an *equalization of wages* that labor in different industrial activities and in various trades will receive approximately the same compensation for similar work.

Equalization of Wages Necessary

It is impossible to continue to pay some trades wages that are two or three time as high as the wages in other trades. It is true that in those trades where steady employment throughout every day in the year is impossible, hourly wages should be correspondingly higher than in those where permanent employment is reasonably assured; but the adjustment should be equitable and proportionate to the reasonable period of employment. The workers in the transportation field particularly, who are assured of a permanency of employment equalled in few other occupations, are receiving proportionately higher wages than the employes in practically any other enterprise. Nevertheless, these men are more actively resisting a readjustment of their wage scales than the members of any other craft or trade; but an equalization of wages will nevertheless become necessary even if industry must pay the price of cessation of activity and unemployment due to strikes and labor troubles.

There is one thing that the labor unions must learn sooner or later—and the sooner they learn it the better it will be for their own well being and prosperity—and that is that you cannot get any more out of an industry than you put into it. If you put into an industry short working hours and inefficiency due to unreasonable rules and regulations, that industry in the long run will suffer and the fund out of which the workers must be compensated will be that much less. If we were all working at all times at the top speed that the piece workers did in the munitions factories during the war, the production that could be shared by all would be that much greater and the possibility for greater returns for labor would increase. It is when the cost of production begins to exceed the price at which the goods can be sold that the wheels of industry stop; if the cost of production could be continuously held below the price that the consuming public is willing and able to pay, the wheels of industry would continue to turn without interruption.

Diamond Alloy—A New Cutting Metal

DIAMOND alloy is a non-ferrous alloy composed mainly of chromium, molybdenum, and tungsten combined in proportions and by processes that result in a metal so hard that cutting tools made from it possess an unusual resistance against wear. Another favorable property is that tools made from the alloy may be used under conditions of feed and speed that raise the temperature almost to the fusion point without there being any tendency of the cutting edge to soften. The metal is non-magnetic, a property that is desirable under certain conditions.

The alloy cannot be forged, but milling cutters, slitting saws, reamers and other tools of this general character are cast in permanent molds, the process assuring a uniform composition of the metal and freedom from blow-holes and other defects sometimes found in cast metals. Some tools are cast on a steel core or center, or on a shank, while others are made entirely from the alloy. The possibility of casting on steel is especially important with such tools as keyway milling cutters where it is desirable to have the cutter at the end of a shank. In such cases the shank is made of chrome-vanadium steel which possesses ample strength to withstand severe service conditions. A flange on the end of the shank has a groove machined around its periphery, and when the alloy is cast on this flange, the groove serves to positively lock the metal against sidewise movement. The same general form of construction is employed in making other milling cutters, slitting saws, chucking reamers, etc., advantage being taken in every case of using a lower priced material of ample strength for the shank.

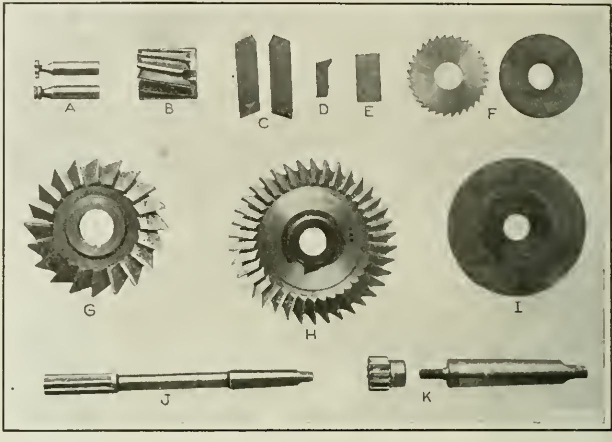

Fig. 1. Typical Examples of Tool Bits and Cutting Tools made from Diamond Alloy

A group of tools made from the alloy is shown in Fig. 1. A keyway milling cutter and shank of the design mentioned in the foregoing are illustrated at *A*, and a shell end-mill at *B*. The blades presented at *C* are for an inserted-tooth milling cutter, and that at *D*, for an inserted-tooth circular saw. A blade blank is shown at *E*. At *F* are illustrated a slitting saw and a solid Diamond alloy blank from which this tool is made. The milling cutters at *G* and *H* are machined from blank *I* on which the alloy is cast on a steel center. The chucking reamer at *J* has the alloy cast on a shank, and spot-facer *K* consists of a Diamond alloy cutter and a separate steel shank on which the cutter is screwed.

Advantage is also taken of the possibility of welding Diamond alloy to steel by making "laminated" tool bits which consist of a strip of the alloy welded to a strip of chrome-vanadium steel. Such a combination provides a tool having both the cutting properties of Diamond alloy and the strength possessed by the steel backing. Laminated tool bits are shown in Fig. 2 at *P*, and tool bits made entirely from the alloy, at *Q*.

The following examples of results obtained with tools made with Diamond alloy will be of interest: In milling cast iron the cutter was run at a speed of 370 feet per minute with a feed of 15 inches per minute and a 1/8-inch depth of cut. In turning machine steel having a carbon content of from 0.35 to 0.40 per cent, the tool was operated at a cutting speed of 125 feet per minute with a feed of 5/16 inch per revolution of the work and a 1/8-inch depth of cut. In turning a chrome-nickel steel shaft, the cutting speed was 125 feet per minute with a feed of 1/32 inch per revolution of the work, and a 7/32-inch depth of cut.

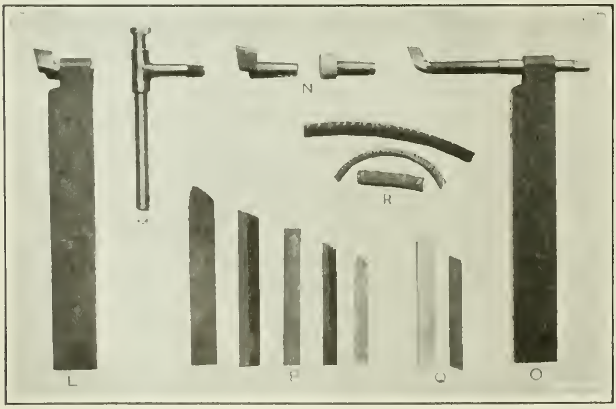

Fig. 2. "Super" Tool-holder and Tool Bits and Diamond Laminated and Solid Tool Bits

Referring to Fig. 2 there will be seen at each end of the illustration a tool-holder known by the makers as the "Super." This tool-holder is intended for use with different styles of cutter bits made from the alloy. It is made in nine sizes with shanks ranging in cross-section from 3/4 by 3/4 inch up to 1 1/4 by 2 1/2 inches. The boring tool *M* and the single-point and round-nose cutter bits *N* have a taper shank which fits into a corresponding socket in the tool-holder. In the case of a single-point bit the same bit and holder can be adapted for service where either a right-hand, straight, or left-hand tool is required, by changing the position of the bit in the holder.

The taper of the shank on the tool bits is very gradual, and as a result the pressure of the cut forces the shank securely into the holder and assures permanence of the bit position without the use of set-screws or other clamping means. This tool-holder can also be furnished for drills, boring tools, etc. Diamond alloy and the "Super" tool-holder are manufactured by the Kent-Owens Machine Co., Toledo, Ohio, and the exclusive selling agent for these products is P. H. Biggs, 1235 W. 9th St., Cleveland, Ohio. The alloy was formerly made by the Diamond Alloy Tool Co., St. Louis, Mo.; it was developed by Walter Brown, who is now manager of the Diamond Alloy Division of the Kent-Owens Machine Co.

STOP FOR AN AUTOMATIC MACHINE

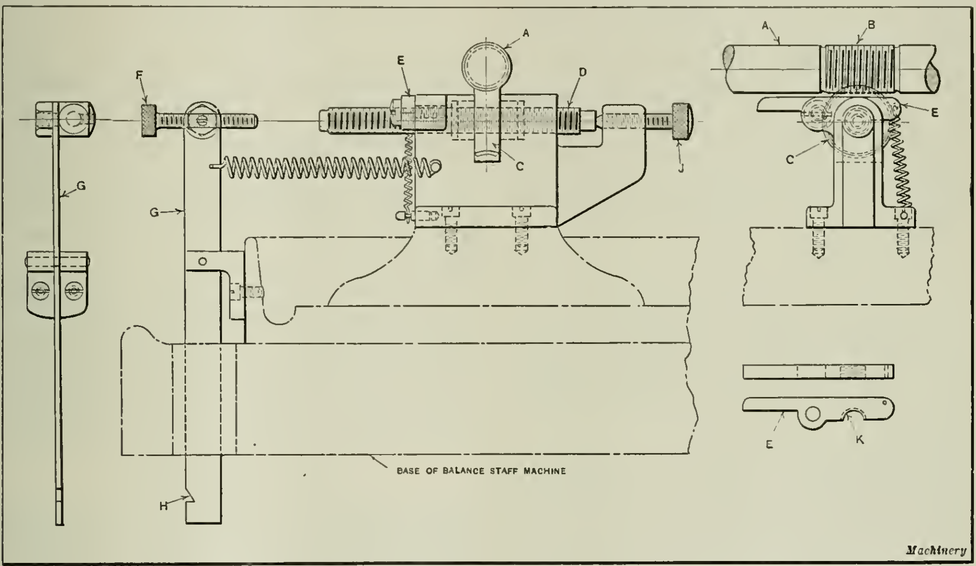
By I. BERNARD BLACK

An automatic stop designed to prevent the jamming of stock in the feeding chuck of a balance-staff machine when the end of the stock has been reached is shown in the accompanying illustration. Several automatic stops were tried out on these machines without success previous to the development of the stop shown. This stop is a modification of the type used on bench screw machines. Before proceeding with the description of the stop it may be well to mention that a balance-staff machine is used for turning the balance staffs for watches. The balance staff is the shaft on which the balance wheel of a watch is secured. At each end of this shaft is a fine pivot. When assembled in the watch these pivots are supported by jewel bearings.

The balance-staff machine is similar in design to a small bench screw machine. It consists of a spindle containing a chuck and a mechanism for feeding the stock forward, a camshaft with a set of cams for operating the chucking mechanism, for reversing and controlling the feed, and for operating the front and rear cross-slides. The front cross-slide carries the cutting-off milling cutter, and the rear cross-slide the milling cutters that form the pivots. It might be added that the balance staff is only rough-milled in this machine; it is afterward put into a pivot-turning machine and the pivots turned down to the required diameter and then polished. During the milling of the pivots and the cutting-off operation, the work is firmly held in a support. The spindle camshaft and the cutters in the cross-slides are all driven separately from the main driving shaft.

In attaching the stop it was necessary to alter the regular camshaft *A* somewhat. A left-hand quadruple-thread worm having five threads per inch with a lead of 0.20 inch and a pitch of 0.050 inch was cut on the shaft at *B*. This worm is employed to drive the worm-gear *C*. When the machine is in operation the camshaft turns the worm-gear *C* which, in turn, revolves shaft *D*. A keyway is cut the entire length of the threaded part of shaft *D*. A key held in worm-gear *C* is made a sliding fit in this keyway. Now as shaft *D* has a left-hand thread which fits the threaded part *K* of piece *E* (see view in lower right-hand corner), shaft *D* will move toward the set-screw *F* when the machine is in operation. When lever *G* is pushed back by the end of shaft *D* coming in contact with screw *F*, the stopping device of the machine, which is controlled by a latch held in V-slot *H*, is released and the machine stopped.

The stock used in the manufacture of the balance staffs comes in three-foot lengths, and the stopping device is set to stop the machine automatically when about 2 inches of stock is left in the feeding chuck. This prevents the jamming of the stock between the cutters and enables the operator to easily take out the piece left in the chuck and to feed in a new piece of stock by lifting part *E* sufficiently to disengage the thread of shaft *D*. The latter member may be pushed back into contact with the stop-screw *J*, when lever *G* will spring back to its former position as shown in the illustration. The machine is then started by lifting up the starting latch so that it will be engaged by the V-slot *H*.



Device for automatically stopping the Operation of a Balance-staff Machine when the End of the Stock is reached

* * *

The Bureau of Fire Underwriters has estimated that the destruction of property by fire in the United States during the five-year period ended with 1920 was $1,672,722,697. Carelessness in the use of matches is said to be the cause of property loss valued at $90,000 000. Spontaneous combustion, lightning, heating systems, sparks on roofs, and defective chimneys are other causes of fire loss named by the bureau. It is safe to say that the fire loss would have been greatly reduced had every property owner given the various causes named above due consideration and taken steps to remove all unnecessary hazards.

Advancement in the Machine Industries

By LUTHER D. BURLINGAME, Industrial Superintendent, Brown & Sharpe Mfg. Co., Providence, R. I.

THE worthwhile opportunities in the machine tool industry which should stimulate young men of ability to train in this field for their life work, have been well pointed out by Fred A. Geier and J. B. Doan in July MACHINERY. It is the purpose of this article to indicate some of the qualifications necessary to take advantage of these opportunities, and the preparatory steps required to make such a career successful.

When the writer entered the machine tool industry nearly forty years ago, he heard many expressions of discouragement from those already engaged in it—expressions to the effect that the "good old days" had gone, that there was no opportunity for men to advance, that there was nothing left for them but drudgery, and that they would advise their sons to go into other lines of work. Notwithstanding these pessimists (whom by the way we still have with us), there has been more progress during these forty years, and wider opportunities have opened up than in all the centuries before; and there is no reason to believe that the next forty years will not show equal and even greater opportunities, and opportunities along more specialized lines, so that each branch of training and of ability can have full scope. Those who are willing to train themselves now, will reap a rich harvest in the future.

Character

No matter what branch of the work is undertaken, there are certain qualifications essential to real success. The first of these is character. Many years ago the late Frederick W. Taylor said in speaking of the qualifications necessary to attain success in life: "Without the slightest question, character comes first, good sense second, and intellectual training third."

The training required to develop character and good sense is more difficult to define in a specific way than that of intellectual training. The former includes the cultivation of a spirit of loyalty, both to superiors and to the business with which one is connected; honesty in its broader sense, which might include faithfulness, promptness, thoroughness, etc.; and energy to prosecute the work in hand. It develops such qualities as are summed up in Hubbard's immortal "A Message to Garcia."

Character is not formed by studying rules in books, but is gradually developed by holding to a high standard through the many temptations in life, emulating the example of great men among contemporaries and acquaintances as well as characters in history and fiction. A man is fortunate indeed who through birth and home training starts his life work with a well-grounded character.

Good Sense

Under good sense might be placed the cultivation of judgment, which in turn can be acquired by learning from the mistakes of others, as well as one's own; by storing up a fund of information with which to measure new conditions as they arise; and by never depending on opinions without checking them up with facts. Intellectual training, through continued and extensive study, can be made an important adjunct to good sense because it gives, in addition to a broad knowledge, the ability to secure desired information quickly even though not carried in the mind. A trained mind that has learned to memorize, to analyze, and to coordinate knowledge, is a tool capable of being used in any emergency or for solving unexpected problems.

Speed and Accuracy

Every employer appreciates speed and accuracy in work, speed being a quality which counts directly in determining the value of designers, engineers, and executives, but which without accuracy may have its advantages entirely offset. Waste from inaccuracy is forcibly pointed out in a little booklet by Jerry McQuade, in which he cleverly shows how what seemed like a small error took the time of thirty-seven men, three women, two boys, and eight horses to correct.

Speaking and Writing

An important stepping-stone toward success lies in cultivating the power to speak and write convincingly. Whether speaking in public or in private, the ability to present forcibly before one or more hearers the reasons for pursuing a certain policy, or for accepting a proposed design, may mean success or failure. The faculty of stating clearly and briefly in a written report what it is desired to impress on others may lead to the acceptance of a plan or the adoption of a policy which, with poor presentation, would not be favorably considered even though good in itself.

The development of this ability can be helped by taking part in the activities of engineering societies, or such other societies as most directly deal with the particular phase of industry for which one is studying. This also can lead to a wide acquaintance, both personal and by correspondence, which is one of the best assets to insure future advancement. Many a young engineer has started on the road toward a wider field of activity by writing for the technical press, and by studying technical books and journals.

The Good Job is the Hard Job

The young man who is looking for an easy job is not likely to be the one who will excel later. It has been well said that "the good job is the hard job." Dr. Taylor, already quoted, says that in examining the careers of those men who have become successful: "It has been found that they are men of singleness and earnestness of purpose; men who have acquired by long training those habits both mental and physical which make them masters over themselves together with a firm determination to pay the price for success in hard work and self-denial."

The ability to serve well is the first qualification for success in directing others. One of the important lessons to learn is that of working with all kinds of people, both as superiors, as shopmates, and as subordinates. The cultivation of such traits as will make a man universally liked and respected by those about him, will prove a valuable possession in the successful handling of men.

Specialized Training

When the specific question is asked: "What shall I study to secure advancement in the machine tool industry?" it at once raises the question as to the definite line for which one is training. In addition to the general qualifications already discussed, the development of which should help in any branch of the work, there are many opportunities to specialize in training. For instance, there is the case of a boy brought up on a farm, with meager education, who when he became an apprentice in a machine shop, spent his evenings studying algebra and geometry. He afterward became eminent as an authority on gearing. Then there is another case of a young man who spent his spare time outside the machine shop studying French and German. He afterward represented his employers at a great exposition abroad and later became sales manager for a company having extensive foreign connections.

Many young men of an inventive turn of mind received much stimulus a generation ago from a series of articles on the Cultivation of the Inventive Faculty, giving problems in mechanisms to be worked out by the reader. One, when asked what studies he expected to pursue during the summer, said that he felt that he would gain the most by studying human nature.

These illustrations show the wide scope of training which may fit one for advancement. Such training might be classified under the heading of the Five M's: Men, Methods, Material, Machinery, and Money, which, generally speaking, constitute the factors in industry.

Men—Learning to deal with the human element, with equal emphasis on the need of learning how to work with the boss and with the workman. This may also include all branches of industrial service work, such as safety, medical supervision, industrial schools, recreation, and Americanization. The ability to meet and deal with men is an important, if not the most important, element of salesmanship.

Methods—The study of shop organization, with its many branches, such as efficiency, routing, etc. Also economical methods of production and elimination of waste.

Material—Raw material; stock to be carried; its cost; its quality, including questions of hardening, heat-treatment, etc., the utilization of scrap; all are subjects worthy of serious study.

Machinery—Cultivating ingenuity and invention; learning simplicity and adaptability of design; tool and jig work, etc.; acquiring a knowledge of the history of mechanical development, including the matter of patents; and competitors' products.

Money—Acquiring proficiency in timekeeping, cost accounting, auditing, credit rating, and general office and business administration.

The Value of Having a Hobby

Besides the study given to the particular line chosen, every man should have a hobby, something that will take his mind entirely off his work. It is not always advisable to devote every minute of one's spare time to studies, even though good in themselves. Some time should be given to activities which tend to widen the circle of vision outside of the professional field. Having a hobby has directly to do with health, because any interest enjoyed as an avocation is conducive to good health. It goes without saying that without a healthy body and a clear mind one is working under a great handicap, which limits success in any line of endeavor.

Any of the various branches of mechanical industry here discussed, successfully mastered, can be made an effective tool for advancement to a position of trust and profit. While study and preparation should not stop with school but be made a part of lifetime activities, it must not be forgotten that the main purpose in life is not to absorb knowledge but to give it out. Success is not attained until a point is reached where instead of assimilating, knowledge is distributed for the benefit and advancement of industry, and the good of the community.

The lines of study here mentioned are merely illustrative. Other lines will be suggested by simply having the requirements stated; and it must be understood that broad and extended experience, in addition to knowledge acquired by study, is the sure foundation on which success in the machine tool industry can be built.

LEARNING VERSUS STUDYING

By A. W. FORBES, Forbes & Myers, Worcester, Mass.

On page 870 of the July MACHINERY is found the statement: "There is much less inclination to devote spare time to study than in the years preceding the war, and the tendency to avoid serious effort is marked." This statement is made about the "younger generation" which probably means those under, say, twenty-five years of age.

It may look that way to manufacturers who are trying to get their younger employes to study for advancement in their work, but a glance at the schools for people of working age gives an entirely different impression. At least in Worcester, school attendance has increased in an astonishing manner, both day and evening. New public and private schools are continually being opened, and the old ones are overcrowded. Does this show a disinclination to study? It would be hard to convince the unprejudiced observer that it does, and yet there is something in the statement quoted. This enthusiasm for schools is rather a desire to be taught than a desire to study. There certainly has been a change in the general attitude, but this change has been more a loss of self-control than a loss of ambition. The modern youth is ready to rely on others to make him into somebody rather than to direct his own course. It must be remembered also that the schools are continually diverting an increasing number of boys from the factories, and that those so diverted are often the ones most inclined to study.

Educators feel that this change is a great improvement. They point with pride to the growing number seeking school education, and are doing all they can to promote the good work. The author is inclined to take the opposite view. The electrical shop of Forbes & Myers, Worcester, Mass., employs a number of boys. Practically all these boys have spent a considerable portion of their spare time in some form of school study, academic, trade, or technical; day, night, or correspondence. While some of this study is doubtless valuable for general culture, particularly the academic, it seems to have no practical value for making progress in the shop.

The kind of study that the boys in the shop are urged to do is the kind that it is most difficult to get them to do; namely, to take up a problem which occurs in connection with the work, and to study it thoroughly, both in books and periodicals, or any other place where they can find information. It was probably this lack of personal effort on the part of the younger generation in the matter of study that was felt by the author of the statement quoted in the first paragraph of this article. Only by such study, however, can the shop employe advance beyond the knowledge that any of the standard courses can give him.

The cause of the changed attitude toward study can most likely be found in the schools. It is not a change that occurred during the war, although the war may have accelerated it. It has been going on for many years. From the kindergarten up the boys must fit into the school routine. At the same time they are being impressed with the value of the school. After a certain amount of study the mind naturally becomes tired, at least to the extent of not looking for problems to solve. With the propoganda urging them toward school study, the boys devote to it practically all the time that they are willing to give to acquiring any kind of knowledge; after that they cannot be expected to start right in again studying their work.

There seems to be actual conflict between the schools and real study that leads to advancement, but this point is not often recognized. A boy whose mind has been thoroughly trained to receive information in the way it is presented in school, is not so well prepared to study by himself as he would be if he had never been to school. Instead of blaming the boy, it might be more just to blame the institution that has failed to teach him the most profitable form of study.

The British Metal-working Industries

From MACHINERY'S Special Correspondent

London, July 14

THE interruptions of the last three months have naturally deranged all branches of engineering industry and some time must elapse before production programs can be straightened out. There has, however, been a grain of comfort in the fact that, serious as the stoppage has been, it might have been disastrous had it not occurred during a period of very limited buying.

In the machine tool trade makers are finding that current demand is confined largely to special machines. Inquiries for standard machines continue and it is generally expected that export trade will be the first to recover. In the ordinary lines of machine tools, both manufacturers and dealers are still overstocked and there is doubt if more than a small percentage of the machine tools sold from Government stock have gone into service. Buyers of machine tools realize that machine tool builders can deliver stock machines to meet any emergency; hence they hesitate to purchase with a view to having equipment on hand for future production.

Machine Tool Prices

Although most machine tool makers are no doubt open to offers for their products, there is no tendency toward a general slump in prices. A substantial decline in machine tool exports or a large influx of foreign tools might have a serious effect on prices, but neither of these conditions is likely to arise. America has a good stock of machine tools in the country but there are no signs of selling at low prices. The downward movement of prices in general is rapidly slowing up, for the simple reason that it is impossible to produce new supplies at a lower cost.

During 1919, when prices had reached a zenith, machine tools averaged two and one-half times the 1914 values; they have now fallen to about twice these values. As general prices appear to be finding a level at about one and three-quarters to twice the pre-war levels, it will be seen that machine tool prices are in keeping with other products. In the machine tool industry several of the costs, such as fuel, railway rates, packing and many general supplies, have risen above the average increase for other commodities. Machine tool makers cannot be held responsible for this.

General Engineering

Motor car manufacturers continue to be in a strong position; demand is unabated and in the trade there is no accumulation of stocks. The disturbance of production systems owing to recent trouble has seriously upset delivery dates and in several sections of the industry multiple shifts are being worked in an endeavor to hasten the lagging production that is holding up delivery of complete cars.

There is a renewal of activity in railway car and locomotive shops, and substantial orders have been or are about to be placed. Among these may be mentioned materials to the value of £60,000,000 to be used in a big scheme of Indian railway reconstruction that has been postponed since 1914. The contracts will take ten years to complete. The Caledonian Railway Co. has ordered twenty new locomotives from the North British Locomotive Co., Glasgow, and the same railway company has placed orders for five hundred cars from Hurst, Nelson & Co., Motherwell.

An improved demand is urgently needed in the marine engineering and shipbuilding industry. British yards, however, are competing with more success for repair work that has been going to the Continental yards. The future is uncertain, and may remain so until the important questions of oil supply and control are satisfactorily settled. Upon this hinges, to a large extent, the type of prime mover which will be installed in the future, and the internal arrangement of the ships themselves.

An order has been placed by the United Fruit Co. of Boston with Cammell Laird & Co., Ltd., for three 4000-ton insulated motor ships. These will be driven by electric motors, with Camellaird-Fullager Diesel engines as prime movers.

The textile machinery trade is active, the demand being well sustained; moreover there are many orders that await completion. Wireless broadcasting is likely to develop very rapidly and the manufacture of the apparatus used in connection therewith will be largely a new industry. In the iron and steel trades, the position shows little change compared with a month ago.

The Foundry Trades Exhibition

The International Foundry Trades Exhibition was held at Bingley Hall, Birmingham, during the latter part of June. Out of a total of 178 malleable iron foundries in this country, 134 are in the Birmingham area; most of the nonferrous foundries and nearly 1000 out of 2800 gray iron foundries are in the same area, indicating the great importance of Birmingham to the foundry trade. The exhibition served to show that there are now quite a number of British firms producing molding machines of all types and sizes. There is also evidence that foundries in this country have developed their technical resources considerably and have at the same time been wide awake to any improvement introduced on the Continent or in America.

Overseas Trade in Machine Tools and New Equipment

During May the exports of machine tools reached a value of only £114,372 as compared with the April return of £171,612. The value per ton rose from £121 to £139. Imports fell during May from 266 to 250 tons for the month, the value per ton falling from £116 to £97. The latter is a lower figure than has been registered for a very long period. How much of these reductions in trade are definately due to the lock-out and its concomitant troubles, it is not easy to say, but last month's returns show a decided falling away from the promise of the previous few months.

Prominent among new machine tools is an 8½-inch lathe by Dean, Smith & Grace (1908), Ltd., Keighley. Since being first placed on the market some eighteen months ago, several new and interesting features have been added. One of them is an arrangement of supports for long lead-screws. At each side of the saddle the lead-screw is supported by jacks that are automatically moved into and out of position by the movement of the saddle as it is traversed. The result is an adequate support and a prevention of any undue sagging, while at the same time there is no obstacle left in the path of the saddle.

The Cambridge & Paul Instrument Co., Ltd., London, have introduced a furnace temperature controller that can be easily applied to any type of furnace fitted with an indicating pyrometer. The controller is suitable for the lowest temperature recorded by resistance thermometers up to the highest temperatures indicated by Fery instruments.

MAKING OVER-SIZE PISTON-RINGS

The manufacture of piston-rings involves skilled workmanship and careful inspection methods to insure the necessary degree of accuracy. The Houpert Machine Co. of Long Island City, N. Y., manufactures over-size piston-rings for its own use in refitting reground cylinders. The manufacturing methods employed by this company in making rings are here briefly reviewed.

Milling the Lap Joint in the Rings

The piston-rings are made from individual castings and are finished all over. They are concentric in form, and are sometimes provided with a lap joint and sometimes with an angular joint. Before cutting the joints, the castings are ground on the sides on a Heald rotary surface grinding machine, and rough-ground on the outside diameter on a cylindrical grinding machine. The method of milling the lap joint is illustrated in Fig. 1. This work is done on a duplex type of hand milling machine, the heads of which are provided with suitable adjustment so that the end-mills may be offset as required to produce the joints.

The rings are abutted against two pins and are located against the scraped surface of the heavy cast-iron angle-plate *A*. A parallel clamp *B* is secured against the opposite side of the ring, and operated by a capstan wheel at the front of the machine. The capstan wheel is fastened to an operating screw, one end of which tapers and extends into a corresponding hole in the clamping member *C*. This member is simply a short shaft, set at an angle in bracket *D*, and provided with an adjusting nut *E* so that various widths of piston-rings can be accommodated. When the operating screw is advanced by the capstan wheel, its tapered end moves member *C* forward, and forces the clamp *B* against the ring. Two coil springs attached to the clamp, one above and one below, free the work when the clamp is released.

This device is attached to the table of the milling machine, and the ring is fed by hand against the end-mills, thus producing the lap joint. When the two cuts that produce the joint have been completed, and the milling machine table has receded, the capstan wheel is turned, releasing the clamp and permitting the ring to drop into a receptacle beneath.

Finish-grinding and Boring

The next machining operation consists of finish-grinding the outside diameters. The rings are taken to a bench, where the grinding arbors are loaded with rings, but before loading on the arbors, the lap joint is faced off slightly at the ends, on the side of a disk grinding wheel. In loading the arbors, the rings are compressed between four high jaws, arranged radially 90 degrees apart on a faceplate, which are adjustable for different diameters of rings. While the rings are thus compressed, the arbor is run through them and they are clamped from the ends. The jaws are then removed and the arbors placed between centers in the grinding machine. The last machining operation required to finish the rings all over is boring. A quantity of rings are arranged in a suitable chuck and a boring-bar fed through them.

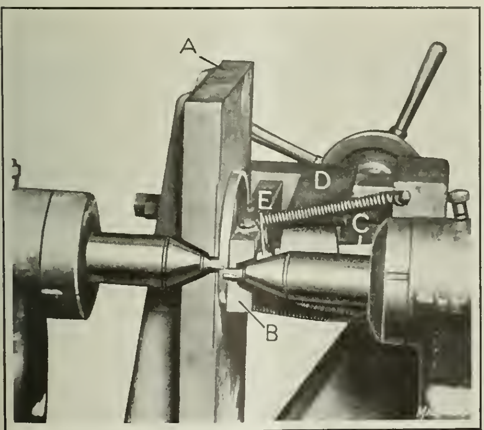


Fig. 1. Duplex Hand Milling Machine with Piston-ring Clamping Device

Fig. 2. Grinding Ends of Lap Joint before gaging for Expansion

Fitting the Rings to the Cylinder Bore

Finally, the rings are fitted to the cylinder bore. Although this is apparently a simple operation, it is of great importance, and the work must be carefully done. An allowance must be made for exactly the right amount of expansion; if the rings fit too tight, the cylinder bore will become excessively worn after being in use only a short time; and if the rings are too loose, the result will be poor compression and a consequent loss of power. The fitting operation consists simply of grinding the ends of the joints to allow the proper amount of clearance after the rings have been compressed in the bore. The operation is illustrated in Fig. 2, which shows a disk grinder and the Norton elastic wheel used. The wheel is 8 inches in diameter by 1/8 inch thick. It is made of No. 46 grain abrasive and is No. 4 grade. A cast-iron gage in the form of a cylinder is used, into which the rings are compressed, the joint being exposed through a slot in the side of the cylinder. Long experience enables the operator to determine with little experimenting the amount of metal that must be removed from each end of the joint in order to furnish the proper clearance.

From time to time a thickness gage is used between the joint, this gage being of proper thickness to agree with predetermined allowances for expansion. These allowances vary, of course, with the sizes of the rings. For example, for a 4 7/8-inch ring, such as here shown, a flat gage 0.010 inch thick is used, although the allowances may range from 0.006 to 0.012 inch. After the operator has ground three or four rings and compressed them into the gage, he removes them and uses the last one to locate the next three or four, usually gaging this locating ring only. Both ends of the lap joint are ground, an equal amount of metal being removed from each.

Effect of Design on Drilling Machine Efficiency

By F. E. JOHNSON

IT is often the case that a machine is lacking in certain essential points of design, with the result that the tools employed are subjected to various kinds of strains, stresses, or shock. Vibration, friction, and deflection of machine members are factors that must be overcome in producing different classes of machine tools. It is proposed to discuss in this article certain important factors in the design and operation of drilling machines, and to advance suggestions for improving the operative conditions commonly found in machines of this type.

The advent of high-speed steel made it compulsory for machine tool builders to make radical changes in the design of their machines in order to meet the new requirements. Many of the earlier types of machines, which were originally designed to employ carbon steel tools, have not been able to resist the strain set up when it was attempted to drive high-speed tools at their maximum capacity. The weaknesses developed also reacted on the tools with a destructive effect. Consequently, the quality of the work was not of the best, production was insufficient, and the expense for machine repairs was high. Vibration in an efficient quantity-production machine must be overcome as far as possible, and in order to do this and prevent the tools from chattering, it has been found necessary to employ mass design wherever practicable. The machine designer, in creating a new product, is almost wholly dependent upon his general knowledge of the successful adaptation of well-known elements of machine construction. The development of a new machine is also contingent upon certain other factors, such as knowledge of minute mechanical details and how they may be best incorporated in the design.

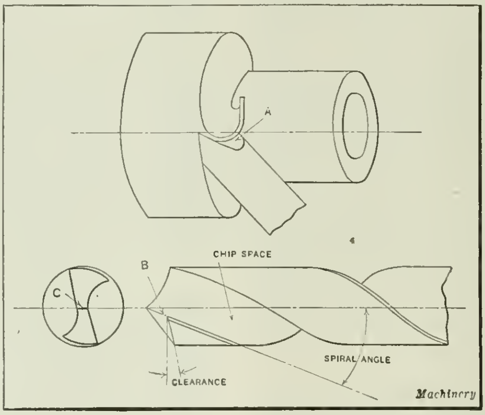

Fig. 1. Diagram used in analyzing the Cutting Action of Twist Drills

Diminishing the Amount of Sliding Friction in Machine Parts

Friction between parts of a machine consumes excessive power for operating. It also produces heat and wear of the parts. The effect of friction is greatest in heavily loaded machine parts which are slow-moving. This includes common slides and sliding shafts. The wear caused by friction decreases as the velocity of the parts increases; for high pressures, the friction is very great at low velocities. If bearing surfaces are flooded with oil, the friction is almost independent of the materials from which the parts are made, because it is the film of oil between the parts, rather than the parts themselves, with which the bearing surfaces come in contact. Theoretically, well lubricated contact surfaces do not bear against each other at all. The matter of sufficient lubrication for machine tools is therefore an important factor in their design.

The frictional losses in a drilling machine represent a large percentage of the power delivered, it being estimated that there is seldom more than one-fifth of this power which is actually transmitted to the point of the drill. This is apparently due to the nature of the cut which the drill takes, which is radically different from the cuts taken by most other cutting tools. By the use of ball and roller bearings, rolling friction is substituted for sliding friction, which results in reduced costs and power for driving the machine. In former times when the common plain type of machine bearing was used, it was impossible to obtain or maintain the velocities necessary in many modern machine tools. At the present time drilling machines, which are fully equipped with ball bearings, are available for operation at speeds ranging from 3000 to 10,000 revolutions per minute.

Direct Application of Motive Power

A point of importance in machine design is to apply power in as direct a manner as practicable. The interposition of a considerable number of shafts or other machine parts between the point of power application and the point of useful application, where power is applied to driving the tools, results in an increase in the total power requirements to operate the machine. The general arrangement of the machine parts in the assembly of a machine, as well as the number of parts which must be used and kept in motion, should always be carefully considered in machine design if most satisfactory results are to be obtained.

Drills and their Cutting Action

There are several rules that influence a machine operator in selecting speeds and feeds which he may safely follow on a particular piece of work with the available equipment. These rules are: (1) If the tool chips out at the cutting edge, the feed is too great or the drill has been ground with an excessive lip clearance; (2) a drill split along the web *C* (see Fig. 1), is evidence of too heavy a feed or of being ground with insufficient lip clearance at the center of the drill; and (3) when the extreme outer corners of the cutting edges wear away it is proof that the speed is too high.

Drills vary in hardness as much as other hardened tools, but the chipping out of steel at the cutting edges under a heavy power feed is more pronounced in drills than in other tools. This fact is due largely to the peculiar and severe duty that a drill performs. The action more nearly resembles tearing the metal than shearing or cutting it. The action of the point of the drill is one of crushing the metal, and this must be done first by the web before the cutting action can be performed by the lips. The drill point itself must be forced into the work and the metal crushed ahead of it before the lips can start to cut. A large drill requires great pressure behind it to bring about this crushing of the metal; for this reason when drilling large holes in tough materials, it is often advisable to start them by first drilling through with a drill of smaller diameter.

The action of the lips of the drill (not the drill as a whole) in removing the metal, is very similar to that of a turning tool, as shown at *A*, Fig. 1. By comparing the general formation of the lip of the drill at *B*, including the lip clearances, the great similarity that exists between the drill at this point and the cutting tool may be noted. By allowing sufficient top rake, the efficiency of the tool shown in the upper part of this illustration could be such that very little power would be consumed in feeding it laterally, as in a turning operation. Excessive top rake, however, gives the tool a tendency to pull itself into the cut, because the force required to curl the chip reacts on the tool. For the same reason, excessive lip rake will make it more difficult for the lips of a drill to curl the chip than to penetrate the work. The spiral angle or rake of a twist drill is, then, an important factor when considering the cutting action of a drill.

Factors Affecting Drilling Machine Efficiency

The speeds and feeds with which a drill may be operated depend largely upon its design and the material from which it is made, as well as upon the nature of the material to be worked. High-speed steel drills may generally be operated at double the speeds permissible in operating carbon steel drills. The length of time during which it is possible to operate a drill continuously under heavy feed, provided it has all the essential requirements of design and durability, depends upon the smoothness and efficiency with which the machine is capable of driving the drill. Weight, stiffness, and rigidity are necessary to counteract and absorb the vibration that is transmitted to the drill point. Rigidity is also required to prevent serious deflection of the machine frame and work-table—deflection caused by heavy feed pressures.

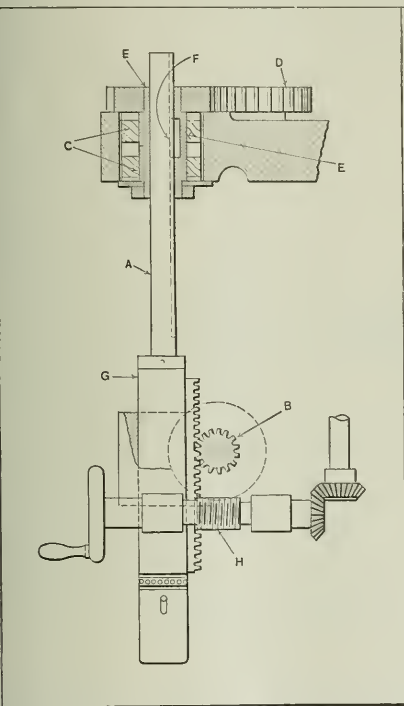

Fig. 2. Drill Feed and Spindle Drive Mechanism of Common Construction

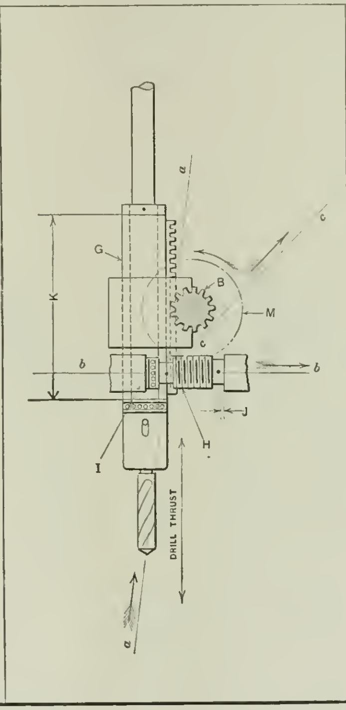

Fig. 3. Diagram indicating Thrusts set up in drilling

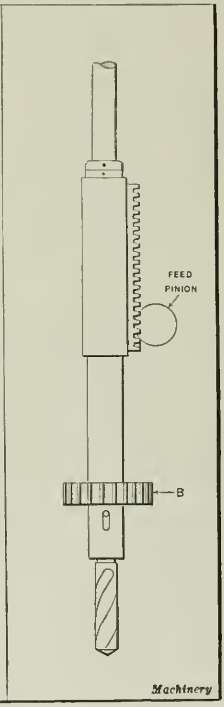

Fig. 4. Drill Spindle with Drive Gear near Nose

The web *C* is not in itself capable of any real cutting action. As previously stated, the duty that a drill must perform is more severe than is imposed on most other classes of cutting tools. The web of a drill must be comparatively thin in order to reduce end thrusts, and also to provide sufficient chip space. A small section is also necessary in order that the drill may cut properly. Because of the resistance which the machining of such metals as steel, wrought iron, and bronze offers, it is sometimes the practice to relieve the bluntness of the drill at the point by hand-grinding.

It has been determined that the feed pressure is greatest where the drill enters the work. At that stage where the lips begin cutting, the feed pressure is reduced somewhat. This is due to the fact that the top face or rake *B* of the drill lips, which is formed by the spiral angle of the drill, is sufficient in certain cases to assist in pulling the drill into the work.

Efficiency of power transmission to the drill point is important in obtaining smoothness of drill feed motion and drill spindle rotation. If the feed motion is irregular or jerky, due to friction, vibration, or backlash of machine parts, the drill point will suffer from continual shocks. It is probable, however, that there are no drilling machines that are not subject to some vibration in a greater or lesser degree, due either to the moving members of the machine or to disturbances caused by floor vibration. In drilling machines on which a heavy power feed is employed, the rate of feed in breaking through a hole is often accelerated over the normal feed, because of the reaction of different machine members which are under strain up to the time that the thrust exerted by the drill is relieved, and because of backlash that exists between the different machine parts. The material being drilled will vary, in many instances, in resisting properties, so that a varying deflection and strain in the operative machine parts is set up, together with a corresponding reaction when the strain is relieved.

Analysis of the Spindle Drive and Feed Mechanisms

The principle of a drill-spindle feed and drive arrangement such as is found in most classes of medium size and heavy-duty single-spindle drilling machines is illustrated in Fig. 2. The drill spindle is indicated at *A*, and the combined pinion and shaft which transmits the feed motion to the drill through a rack, at *B*. All the shafts which are interposed between the main driving pulley or motor and the mechanism indicated in the illustration may be mounted on ball or roller bearings to avoid frictional losses in the driving power. The friction caused by driving the drill spindle is generally relieved by placing ball or roller bearings at *C* to relieve the side thrust exerted by gear *D* upon the spindle drive gear. This driving gear is made fast to sleeve *E*, or the sleeve may be an integral part of the gear. The sleeve drives the drill spindle by means of the gear and a key *F*. It is customary to place a ball bearing at the lower end of the spindle sleeve *G* to receive the thrusts due to the feed. This ball bearing should be provided with a dust-proof cover to protect it from grit and flying particles which would cause injury or excessive wear. Before the use of a ball bearing at this point in the construction of a drilling machine became common, it was the custom to use steel and fiber washers in order to reduce heating and friction.

Heavy-duty drilling machines must be constructed with a very rigid frame. A serious deflection of the frame of a drilling machine due to heavy feed pressures results in a drill binding in the sides of the hole. Great pressure is brought to bear upon one side of the key *F* due to the resistance offered to the rotating action of the drill by the work. The resistance of the work sets up torsional strains in the drill spindle and drill, which is similar in effect to the results produced by the torsional strains in a shaft. Drills are most often broken, or shank ends twisted off, because of excessive strains of this kind. Breakage generally occurs when the drilling of a hole has been nearly completed, and where the drill point is about to break through.

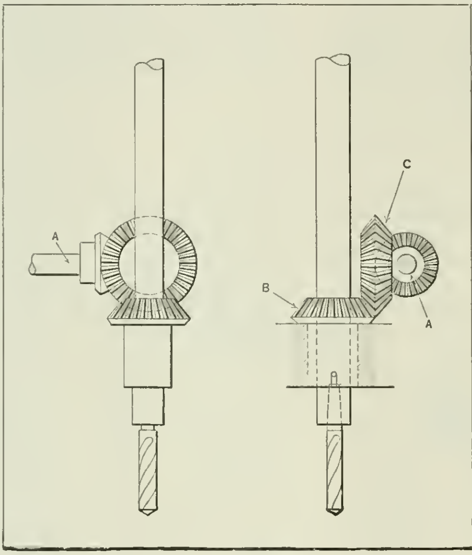

Fig. 5. Radial Drilling Machine Spindle with Drive Gear brought Close to Spindle

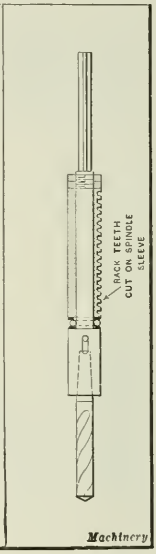

Fig. 6. Spindle with Rack cut in Sleeve

The side strain on key *F* is sufficient in heavy-duty work to prevent a smooth sliding action of the machine spindle. When the feed is engaged, the key slides in a long keyway in the spindle, and when the key is subjected to considerable side strain, this results in a binding effect on the spindle. The action of a drill spindle when great strain is imposed upon the key is particularly noticeable in tapping holes of large diameter, because the spindle must be forced forward or the threads will be stripped. Special tapping chucks containing ball-bearing keys are now being manufactured, by the use of which rolling friction is substituted for the sliding friction produced in the keyway of an ordinary drilling machine spindle.

A large amount of the thrust of a drill is taken by the slow-moving pinion-shaft *B*. The friction at this point is very great under heavy drill pressures, necessitating extra power to operate the machine. It is the practice to mount this shaft in plain bearings, since it is not a rotating shaft in the same sense as are other shafts contained in the machine. On most jobs this shaft is not required to make even one complete revolution during the entire feeding movement. If it were practicable to use ball or roller bearings to support the shaft at this point, the amount of power consumed in operating the machine, when engaged in heavy-duty work, would be greatly reduced. In addition, the increased smoothness of drill feed motion transmitted to the drill by thus eliminating much of the friction at this point, would result in more efficient operation of the machine. Reduced abrasion of worm *H* and the worm-wheel with which it engages would lessen the possibility of backlash between these two members. There is also a certain amount of friction developed between the spindle sleeve *G* and its bearing on the machine frame, due to the side thrust exerted by pinion *B*.

Fig. 3 illustrates certain other points in drilling machine construction which directly affect the efficiency of a drill. The pinion-shaft *B* which is keyed to the worm-wheel *M*, transmits the feed motion to the drill spindle rack through the rotation of worm-wheel *M* by worm *H*. The thrust produced by feeding the drill into a piece of work is indirectly transmitted to the face of the worm-shaft bearing *I*. The worm, in feeding the worm-wheel *M* in the direction indicated by the arrow, meets with resistance to motion which has the result of forcing it back against this bearing. This results in great friction being produced at this point.

Line *a-a* represents the force which is set up by the drill feed pressure, and *b-b* the resistant force produced as explained in the foregoing. The line *c-c* is the resultant of the two forces which act upon the pinion-shaft *B*, the direction of the different forces being indicated by arrows. Efficient drilling machines equipped with a drill feeding mechanism of the type described should have a ball thrust bearing between the end face of the worm and the end face of bearing *I*, as shown in the illustration, in order to reduce the friction generated at this point.

Action of Drill-feed Mechanism under Heavy Duty

In following out and studying the action which takes place in the drill-feed mechanism under heavy duty, and its effect on the drill, it may be assumed that the material to be drilled is machine steel and that the pressure exerted by the pinion-shaft *B* is 200 pounds. When the drill has nearly passed through the work, the strain upon the drill spindle driving key *F*, Fig. 2, is relieved, because the resistance to driving the drill spindle offered by the work is reduced. The power necessary to force the point of the drill into the work is not a factor at this stage of the drilling operation. The result is that the grip of the key on the spline in the drill spindle is partly released. Simultaneously the energy stored in the drill spindle causes it to be thrust forward an amount depending partly upon the backlash in the different machine members, as emphasized in discussing factors bearing on operative efficiency. The cutting lips of the drill (not the point) are not capable of offering great resistance to the accelerated feed movement thus brought about. If the rake on the lips is excessive, there is an increased tendency for the drill to pull itself through the hole which is nearly completed. The weight of the spindle and sleeve will assist in causing an accelerated feed movement if the spindle sleeve moves freely in its bearings and if backlash exists between the spindle rack and the feed pinion.

If, in the drilling process, the machine frame is sprung upward and the work-table downward, the reaction of these members, when the strain upon them is released, combines with the other factors mentioned, to impose a severe torsional strain upon the drill. The general effect of these conditions upon the drill, together with the excessive torsional strain imposed upon it, results in breakage of the drill. The chipping of drill lips when a heavy rate of feed is used is undoubtedly due, to a great extent, to the reasons mentioned. If the material being machined is comparatively soft, such as brass, for example, the tendency to increase the feed movement in the drill at the point where it breaks through the work is naturally greater. The turning of brass requires a cutting tool with negative top rake in order to prevent it from hogging into the work, and for the same reason it is necessary when machining brass with a twist drill to grind the lips by hand so that they have no top rake at the cutting edges.

Backlash between the different machine parts, due to wear or to improper fitting, may prove to be highly detrimental to the operation of the machine under certain conditions. In such cases a positive motion in its true sense does not result from the combination of so-called positive machine members which are involved.

Play and lost motion in the drill feed mechanism illustrated in Fig. 3 may result from wear or improper fitting at *J* and between the teeth of worm *H* and worm-wheel *M*. A worn condition of the spindle rack and the pinion *B* also results in developing backlash at this point. If the adjustment at *K* where the drill spindle is contained in sleeve *G*, is not properly made, the play at this point may be serious when there is a tendency for the drill to pull itself ahead as it breaks through. Play between the spindle and the sleeve would partially offset the advantages resulting from having all other operating conditions satisfactory.

Examples of Drilling Machine Spindle Drive Construction

Fig. 4 shows a drill spindle which has the drive gear *B* applied at a point close to the nose of the spindle. This construction is used in a certain make of radial drilling machines. The objective aimed at in this design is the elimination of torsional strains developed in the spindle when engaged in heavy-duty drilling. A portion of another radial drilling machine spindle drive is shown in Fig. 5. Here the spindle driving gear *B* is also brought close to the drill. Another feature of design is the elimination of as many intermediate driving shafts as possible between the motor and the drill spindle, in order to reduce friction. In attempting to eliminate torsional strains, the main drive shaft *A* has been brought close to the drill spindle by interposing a double-faced bevel gear *C* between the driving shaft bevel pinion and the spindle driving gear.

In order to reduce side thrust and to apply power more effectively, it is desirable to have the drill feed pressure applied as close to the axis of the drill spindle as possible. This is effected in certain makes of machines by cutting the rack teeth directly in the sleeve, as shown in Fig. 6, instead of employing a separate rack, as in the most common construction.

SCARCITY OF LABOR AND INCREASED DEMAND FOR MACHINERY

By ERNEST F. DuBRUL
General Manager, National Machine Tool Builders' Association

It is well to consider the present situation of the labor market. In many quarters there is even now some scarcity of labor, particularly skilled labor. The restriction of immigration certainly makes for a scarcity of common labor that will become evident as the building program progresses. It is said in the Pittsburg and Chicago districts that it would be impossible for the steel works to operate at more than about 70 per cent of their capacity, because of the scarcity of common labor.

The machine tool builder during the war did not train any all-around skilled labor. His orders came in such quantities that he was able to train and use more specialists, and as a matter of necessity he did not find time, even if he had the disposition, to train a more general class of workmen. Now that his orders are likely to be for smaller quantities, he is going to need more all-around men. Even most of the specialists that he trained and laid off after the boom have drifted into other industries. When the demand for machine tools becomes great enough to absorb all the stocks that are now on hand, the machine tool builder is likely to find himself in a bad labor market, with his costs considerably higher than he may now anticipate. It would not then be surprising to find labor costs as high as they were, and perhaps even higher, because of the smaller quantities to be produced with a very great shortage of good mechanics to produce them. It would appear that a machine tool plant that would accumulate a reasonable amount of stock now, would be doing the wise thing.

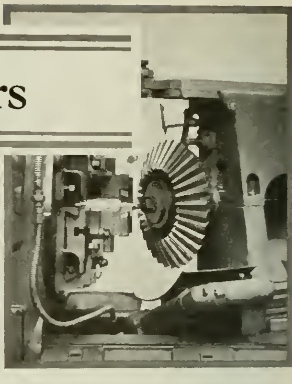
Scarcity of labor will naturally have another influence on the demand for machine tools by making it necessary for the world to use more machinery of all sorts than heretofore to supply its wants. Of course, a great deal can be done to use present machinery and equipment with more efficiency. "The Report on Industrial Waste" shows a great field for this, and scientific management and industrial engineering can develop methods for producing more with the same amount of equipment. But most managers are not able to apply scientific management very freely, and as the growing scarcity of labor becomes more apparent, there will be a natural increase in demand for industrial equipment of all kinds. Machine tools form about 25 per cent of the demand for all sorts of industrial machinery, according to the United States Census of Manufacturers. The man who is in need of equipment of any kind would do well to anticipate his requirements. It will not take much activity to create a demand in excess of the supply in a restricted labor market.

* * *

SAVINGS BY MODERN EQUIPMENT

The machine tools for which there is the greatest demand are those which can be shown to definitely reduce production costs. One manufacturer mentions how, by installing an automatic milling machine, he is able to produce forty parts of a certain product a day as compared with fourteen parts previous to the installation of this machine. In another case, a builder of railroad cars by installing a better drilling equipment than that formerly used, is now drilling seven hundred holes in an eight-hour day, using one operator. In the past, eight operators were required to drill that number of holes in one day. Improved facilities are the order of the day, and savings are made not only in the greater efficiency of machines, but also in the handling of the work. The installation of a certain type of hoist in an automobile plant may be mentioned as an example of the savings that can be made in the proper handling of work. This hoist saved its cost in two weeks.

Cutting Bevel Gears



Principal Adjustments Required in Setting up Gleason Bevel Gear Generators and Time Required for Cutting Gears of Different Sizes and Pitches—Second Installment

By FRANKLIN D. JONES

THE types of Gleason bevel gear generators to be considered first are used for cutting "straight-tooth" bevel gearing. The term "straight tooth" is used to distinguish between the ordinary bevel gears and so-called "spiral bevel" gears. These generators are so designed that the generating motion is applied to both the gear and the planing tools, as shown by the diagram Fig. 2, of the previous installment; that is, the machine operates on the principle of a gear and crown gear rolling together. In fact, segments of these gears are actually used to obtain the required generating or rolling motion between the gear blank and the cutting tools. These machines are used almost exclusively for finishing the teeth of gears that have been roughed out on machines especially adapted for this purpose. Special roughing machines will be considered in an article to be published later.

The bevel gear planer shown in Fig. 1 is an 18-inch size. A rear view of a similar machine set up for planing a gear of larger size is shown in Fig. 2. An important feature of the Gleason generator is that it has two tools for planing opposite sides of a tooth. One tool is cutting on the forward stroke while the other tool is returning, and each tooth is finished before the gear is indexed to present the next one to the cutting tools. The use of two tools increases production, and by operating the tools in opposite directions, vibrations are minimized.

The crown gear segment *A* (shown in Fig. 2) is attached to the outer end of the frame carrying the tool-slides. The master gear segment *B* is bolted to a large yoke or "generating arm" *C*, which is pivoted at one end and is connected to the work-spindle sleeve at the other end. This is a splined connection, so that the spindle sleeve oscillates with the arm, but may be adjusted longitudinally for setting the gear to be cut, so that the apex of the pitch cone coincides with the "center of the machine."

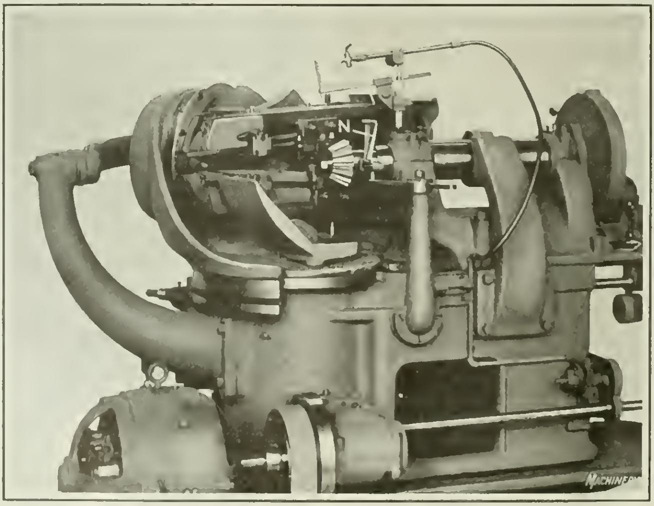


Fig. 1. Gleason 18-inch Bevel Gear Generator

When the machine is at work, the generating arm is slowly oscillated or given a swinging movement upward and downward by means of a cam acting through a slotted elevating arm *D* and adjustable connecting link. This motion is imparted to the gear blank and, through the master and crown gear segments, to the cutting tools. The tools represent the sides of mating crown gear teeth of the same pitch and pressure angle as the gear being cut. They follow lines converging toward the apex of the pitch cone, and, since the rotary motion between the gear blank and the reciprocating tools is like a crown gear revolving in mesh with a finished gear, teeth of the correct curvature are generated.

The diagrams in Fig. 3 show how a roughed out tooth is formed as the gear and tools roll together. Diagram *A* shows the tools at the beginning of the generating motion, diagram *B* the central position, and diagram *C* the completion of the cut. The tools are first swung inward to the cutting position (diagram *A*) by a cam; then arm *C* (Fig. 2) swings upward slowly until the particular tooth being planed rolls around out of contact with the tools, as shown by diagram *C*. During this generating movement, the two planing tools are taking a succession of cuts across each side of a tooth.

Order of Movements for Single- and Double-roll Machines

Most of the Gleason machines designed for cutting gears by a generating process finish a tooth during one rolling or generating motion as just described, but some machines repeat the generating action, and the tooth receives a light finishing cut during the second part of the movement. The first or single-roll method is illustrated at *A*, Fig. 4. After the tools are in the proper position for cutting teeth of the required depth, there is an upward generating motion, during which the sides of a tooth are finished, as explained in connection with Fig. 3. The tools then back out (or the work swings away as on certain other designs of Gleason bevel gear generators), and, after the indexing movement, the tools again feed in to depth; backing out, indexing, and feeding in occur during the downward rolling motion, as the arrows indicate.

Diagram *B*, Fig. 4, illustrates graphically the action of a double-roll type of generator. After the tools feed in to the cutting position, there is an upward generating movement the same as when using a machine of the type referred to in connection with diagram *A*. While the tooth thus formed is accurate enough for practically all purposes, some manufacturers requiring gears of extra fine quality consider it preferable to take a second very light finishing cut. On a double-roll generator this is done (as represented by diagram *B*) by simply reversing the generating motion, thus allowing the tools to pass again across the tooth surfaces while returning to the starting point; the tools then back out and the work is indexed. Most of the Gleason "straight-tooth" generators, and all of those used for spiral bevel gears, are of the single-roll type (diagram *A*).

A third cycle of movements, shown by diagram *C*, and known as a "completing" cycle, may be employed, although this arrangement is seldom used and is adapted only for machines cutting gears of small pitch, which can be finished complete "from the solid," during a single generating movement; the backing out is followed by indexing.

General Procedure in Setting up a Machine

The principal adjustments required in setting up a Gleason generator of the type shown in Fig. 1 will be explained without attempting to cover every step in minute detail. In order to understand the reasons for different adjustments, it is well to remember that the turret or base carrying the tool-slides is adjustable about a vertical axis, which coincides with the horizontal axis of the work-spindle. The gear blank must be so located that an imaginary point representing the apex of its pitch cone coincides with this vertical axis. This central point is known as the "center of the machine." The turret carrying the tool-slides is adjusted about this vertical axis in accordance with the angle of the gear to be cut. Another angular adjustment of the tool-slides is required for the reason that the opposite sides of a bevel-gear tooth converge toward the apex of the pitch cone. To secure this adjustment, the tool-slides at one end are arranged to swivel about a bearing, the horizontal axis of which coincides with the center of the machine.

The mechanism operating the generating arm which carries the master-gear segment must be adjusted to give the arm the right amount of throw, and a suitable master gear must be attached to the arm. A series of master gear segments are supplied with the machine to provide for different angles. The number of strokes per minute made by the tools is regulated by change-gears, and the length of stroke is governed by changing the radial position of the driving crankpin. The indexing movement is also regulated by change-gears selected (by referring to a table) according to the number of teeth in the gear to be cut. After a gear is finished, the machine is stopped automatically by a mechanism that is set according to the number of teeth in the gear. The different adjustments and the general method of arranging the machine for cutting gears of a given size and pitch will now be explained in somewhat greater detail.

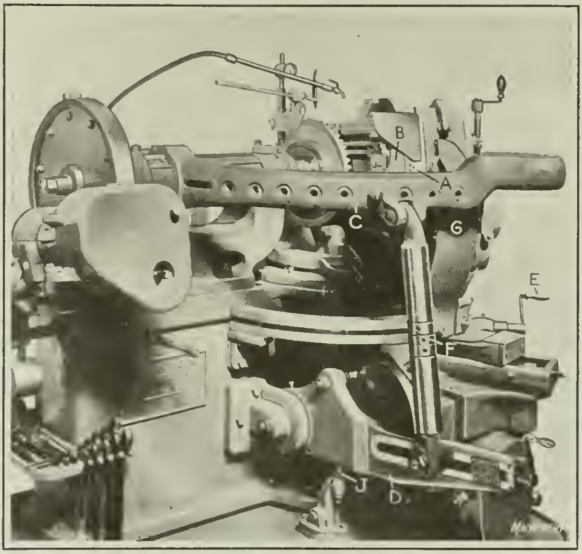

Fig. 2. Rear View of an 18-inch Generator

Tools Used on Bevel Gear Generator

The tools are selected according to the pitch and pressure angle of the gear teeth to be cut. The angle *a*, Fig. 5, of the tool is the same as the pressure angle of the gear. The length *L* must not be less than the tooth depth at the large end, and the width *W* of the point should be at least 0.015 inch less than the width at the bottom of the tooth space measured at the small end.

Fig. 6 illustrates how the tools are set. A gage *A* is held firmly against the tool-slide arm, and tool *B* is first adjusted, by means of adjusting screw *C*, until the point or end just clears the gage. The wedge adjusting screw *D* is then used to shift the tool vertically until the cutting edge is within, say, 0.0005 inch of the gage. The lower tool *E* is set in the same manner, after applying the lower gage to the lower arm.

Angular Position of Tool-slide Arms

The two tool-slides are set at an angle to each other, because of the converging form of the teeth to be cut, by means of suitable graduations. The tooth angle used in making this adjustment is given on a chart; the tangent of the angle may be obtained as follows: Add to one-half the thickness of the tooth at the pitch line the product of the flank depth or dedendum times the tangent of the pressure angle, and divide the result by the cone distance.

The travel of the turret that supports the tool-slides is regulated by adjusting the cam-lever through which this turret is operated. The required angular movement of the turret may be found by subtracting the root angle of the gear from one-half the included angle of the blank and then adding one degree. This turret is set to the root angle of the gear to be cut, adjusting crank *E*, Fig. 2, being used for this purpose after certain nuts have been loosened.

Before making this adjustment, a "double-roll" machine (11-inch and 18-inch) is started and is allowed to run until elevating arm *D* has passed its upper position and has lowered slowly on jack *J*. This jack serves to hold the arm in its mid-position, and is used for certain adjustments to follow. With "single-roll" machines (3-inch and 6-inch) the adjustment for the root angle is made when the generating arm is at about the middle of its "up" roll.

Adjustments of Master Gear and Crown Gear Segments

The gear segment on the generating arm is selected by reference to a chart. Each segment in the series supplied with the machine covers a certain range of pitch cone angles, and the selection is based on the angle of the gear to be

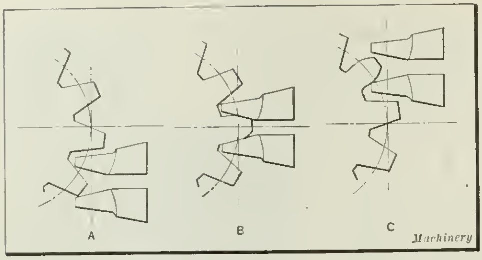

Fig. 3. Diagrams showing the Manner in which Gear and Planing Tools roll together

cut. As Fig. 2 shows, the generating arm has a series of bolt holes so that any gear segment that is used can be located according to its angle. The crown gear must be set according to the block angle, which is the difference between the root angle and the pitch cone angle. Graduations on the crown gear are used for this purpose. A marked tooth on the segment is placed in the center space of the crown gear, and the segment can be centered in the crown gear by adjusting turnbuckle *F*. Just back of the crown gear there is a spring-supported thrust-block that is carried by brace *G*, which also requires adjustment.

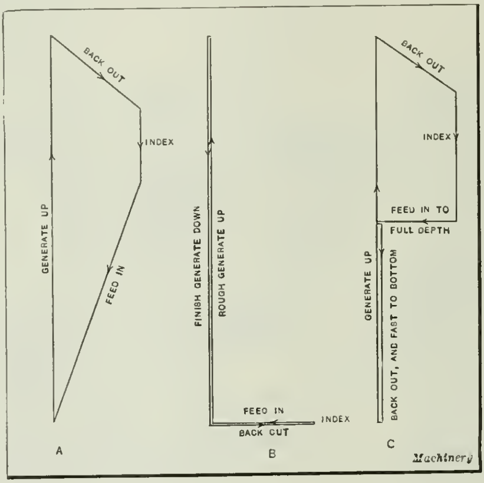

Fig. 4. Three Different Cycles of Movements employed on Bevel Gear Generators

Regulating Extent of Rolling Movement

The rolling or swinging movement of the generating arm is regulated by adjusting the lower end of the connecting-rod along the slotted elevating arm *D*. The diagrams (Fig. 3) illustrate, in a general way, the amount of rolling motion necessary between the tools and the work. When the tools swing in at the proper point, as shown by diagram *A*, and then roll upward with the work until they have stopped cutting, as in diagram *C*, any additional rolling motion is unnecessary.

On the elevating arm *D*, Fig. 2, there are graduation lines to assist in regulating the rolling motion, and numbers indicating the corresponding segment number for each position. To begin with, the connecting-rod can be set according to the number of whatever segment is being used, because this position is based on the greatest pitch cone angle for which the segment is intended. If the pitch cone angle is smaller, the rolling movement can be increased accordingly. The smaller the angle, the greater the amount of roll necessary. The swinging movement is equalized by turnbuckle *F* at the center of the connecting-rod, so that when the cam-lever is resting on jack *J*, the tool-slide frame is in the zero position. This adjustment is checked by starting the machine and noting the angular movement each side of zero.

Endwise Adjustment of Gear Blank

In order to locate the gear to be cut so that the apex of the pitch cone coincides with the center of the machine, the head that carries the work-spindle is adjusted along the bed until a cone distance gage *H*, Fig. 7, shows that the gear blank is in the correct position. With the cam-lever *D* on the jack *J*, Fig. 2, the machine is run until the turret has moved to its extreme outer position. The machine is then operated by hand until the turret has moved in to the face angle. Sliding bar *K* (Fig. 7) of the cone distance gage is next adjusted until the zero lines coincide. The gage is then placed on the tool-slide arm as shown, and after loosening the binder bolts, the work-spindle head is moved up by means of an adjusting crank; at the same time the gage is moved along the arm until the zero lines at the top of the gage pointer *L* meet when the lower end of the pointer is in contact with the top of a gear tooth at the large end.

After one gear of a lot has been set in this manner, the machine is run until the turret stands at the root angle and the generating yoke is about level. This will be at the middle of the down roll for the 11-inch and 18-inch generators, and at the middle of the up roll for the 3-inch and 6-inch sizes. Then the slide on the cone distance gage is loosened, and the gage is placed on the arm with the bottom of the pointer at the outside edge of the gear. The slide at the top is again set so that the zero lines coincide, and this gage setting can be used for the remaining gears when the turret is at the root angle and the arm in about its mid-position. The backing gage *N*, see Fig. 1, is convenient for gears having a pitch angle of less than 45 degrees, which are usually called pinions. After setting the first pinion, the plunger of this backing gage is placed against the back angle of the pinion about half way down the tooth, and it is adjusted until the zero lines of the gage coincide. The gage is then used for setting all the other pinions, and when set in this way the pinions will run flush at the back angles, even though the outside diameters vary, provided the first pinion was correctly set. A gear of accurate outside diameter must be used for the first setting.

Equalizing Stock Removed

The gear to be cut should be so adjusted that practically the same amount of stock will be removed from opposite sides of the roughly formed teeth. This is done simply by centering one tooth between the two tools. In order to turn the gear for centering a tooth, the clutch on the worm-shaft of the index mechanism is disengaged, and one half

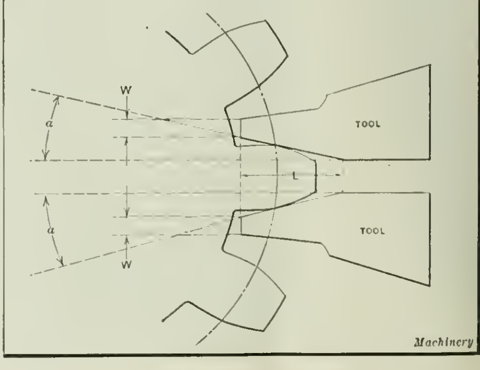

Fig. 5. Angles and Dimensions to be considered in selecting Tools

is shifted relative to the other half. The amount of adjustment is determined by starting the machine and then stopping it when the block angle (or dedendum angle) is at zero, as shown by the crown gear graduations, the cam-lever having been left in the mid-position on its jack, as when adjusting the work-spindle head.

With the crank-plate adjustment slot horizontal, and the crankpin at the forward end of its stroke, both the upper and lower tool-holders are shifted until the tools are about half way through the tooth spaces. Next, with the clutch disengaged, the indexing worm-shaft is turned with a crank until the gear tooth is in contact with the upper tool. A straight line is then drawn across the clutch sections with crayon or pencil. The worm-shaft is next turned in the opposite direction until the tooth touches the lower tool lightly, after which a line is drawn across one side of the clutch opposite the line previously drawn on the other side. The worm-shaft is now turned backward until the single line on one half of the clutch is midway between the two lines on the other half, thus centering the gear tooth between the tools. The clutch sections are then locked together.

After one gear has been set relative to the tools as just described, the stock dividing gage shown at *M*, in Fig. 7, may be used for locating all the other gears. This gage has a swinging pointer, the lower end of which is inserted between two teeth. The gage is set so that the zero lines at the top of the pointer coincide when the lower end is in a tooth space and touching both teeth.

The planing tools should have a cutting stroke equal to the face width of the gear plus 3/4 inch, with an over-travel at the small ends of the teeth of about 1/16 inch. The tools are held in swinging clapper-boxes which provide relief during the return strokes and prevent the tools from dragging and becoming dulled rapidly. These clapper-boxes are returned to the cutting position by friction rods, which slide through adjustable friction boxes.

Time Required for Cutting Bevel Gears

The total time required for cutting bevel gears on generators varies considerably in different plants, because it may be affected decidedly by the method of roughing the gears, as well as by the material of which the gears are made. When gears are stocked out and finished on a generator, the cutting time is greatly increased, although this practice

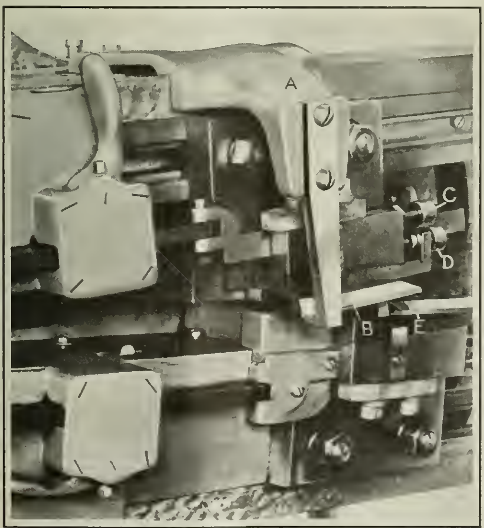

Fig. 6. Gage in Position for setting Upper Tool

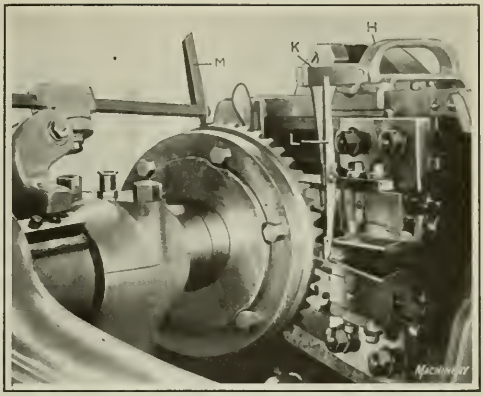

Fig. 7. Gages used for setting Gear in Correct Position for cutting

may be justified under certain conditions, as when gears are cut on a small scale. Even when gears are stocked out on other machines, the total cutting time for gears of a given pitch and material often varies widely, owing to the use of different types of machines. In the large automobile plants where work is done on such an extensive scale that the use of highly specialized roughing machines is warranted, the time for the roughing operation is a relatively small percentage of the total time.

In connection with cutting speeds, it is well to consider the relation between the speed and the period of effective cutter operation between successive grindings. Thus, when establishing an economical cutting speed, it is necessary to take into account the loss of production due to time required for changing cutters and the cost of grinding dull cutters, as well as the increased production obtained by higher cutting speeds.

The following rates of production representing the performance of Gleason generators are not given as records nor as examples that are considered unusual, but rather as average rates which have proved satisfactory in actual practice. These figures relate to the time required for finishing the teeth of gears that have been roughed out on other machines.

Rates of Production for Straight-tooth Bevel Gears

When using a 6-inch generator and cutting differential gears of 5–7 and 6–8 diametral pitch, the time per tooth usually varies from 12 to 15 seconds. In one instance the time for pinions having twelve teeth of 5–7 diametral pitch was 12 seconds per tooth, and the floor-to-floor time, 5 minutes. When using 11-inch and 18-inch generators for cutting steel gears, the rates for different pitches were as follows: 3 diametral pitch, 72 seconds per tooth; 4 diametral pitch, 60 seconds per tooth; 5 diametral pitch, 50 seconds per tooth; 6 diametral pitch and smaller, 36 seconds per tooth.

When cutting cast-iron gears, these rates vary as follows: For 3 diametral pitch, 60 seconds per tooth; 4 diametral pitch, 50 seconds per tooth; 5 diametral pitch, 42 seconds per tooth; and 6 diametral pitch and smaller, 30 seconds per tooth.

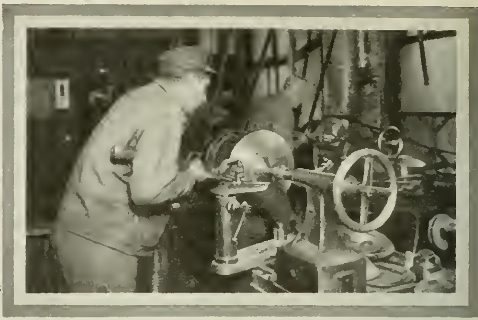
An international exposition of the mechanical and electrical industries will be held at Ghent, Belgium, from June to October, 1923. The exposition will be held in the buildings of the Ghent World's Exposition of 1913. It is planned to exhibit practically all classes of machinery, including machine tools, woodworking machinery, and industrial machinery in general. For information, address Comite de l'Exposition de 1923, Royal Casino, Parc, Ghent, Belgium.

Metal Spinning and Spinning Tools

By EDWARD HELLER



METAL spinning is employed mainly for two classes of work: (1) for removing wrinkles formed on shells during the drawing process, and (2) for producing shapes that are too difficult to draw by means of dies or that would cost too much when made in that way. Spinning to remove wrinkles from shells is by far the simpler of the two applications. Deep-drawn shells made of a comparatively light gage metal such as is used in the making of kitchen utensils and certain kinds of electrical goods, are hard to draw without wrinkling unless the part is cylindrical, and even cylindrical shells are at times slightly wrinkled. The quickest and cheapest way of getting rid of such wrinkles is by a spinning operation. Spinning lathes are made in various sizes for practically all kinds of "automatic" spinning, and as they are standard machine tools, a description is scarcely necessary. The tools used in spinning, however, are of interest.

Spinning Outfit for Removing Wrinkles on Steel Shells

A plain spinning outfit used for removing the wrinkles on a steel shell having a rounded bottom is shown in Fig. 3. The spinning chuck *A* is made from 0.85 to 0.90 per cent carbon steel, and the tail-piece *B* is an iron casting. Stem *C* of the chuck is of such size and shape that it is adaptable to many kinds of work and could well be adopted as a standard. The thrust bearing *D* supplied for the tail end could also be standardized, as it may be used with many classes of spinning tools. The bearing proper is held on the tailstock spindle by means of a set-screw. The tail-piece *B* revolves on a projecting stem to which it is held by a set-screw. The projecting stem is stationary, being a pressed fit in bearing *D*, and supports one race of the ball bearing provided in back of the tail-piece.

Spinning is done by means of the tool-steel roll *E* mounted on a hardened and ground shaft *F* which is a pressed fit in the roll and is provided at each end with a roller bearing in bushing *K*. This entire unit is held in the cast-iron holder *G* by two side plates *H*, which are fastened to the holder by means of flat-head screws. The diameter of roll *E* is usually about 5 inches, except when projecting flanges or other obstacles necessitate a larger diameter. The shank of the holder is about 2 inches square, and is finished on the top and bottom sides to insure a good bearing on the lathe carriage.

The space between bushing *K* and shaft *F* is entirely filled with rollers except for an allowance of about 0.001 inch between each roller for lubricant. The shaft and bushings must therefore be made to close dimensions. It is advisable to keep the rollers of a standard size, and so, obviously, the diameters of the shaft and the bushing on the inside will be decimal numbers. The proper shaft diameter can be quickly determined by making use of the formulas and tables of constants given on page 485 of MACHINERY'S HANDBOOK. Taking the bearing in question as an example, it was decided to use 1/4-inch diameter rollers, and the requirements of the job necessitated that shaft *F* be at least 1 inch in diameter. By laying out the bearing it was found that sixteen rollers would be required to surround the periphery of a shaft approximately 1 inch in diameter. Then by using the formula for finding *R* on the page referred to, and using the constant given in the extreme right-hand column for sixteen rollers, it was found that the diameter of shaft *F* would be 1.0314 inches if the rollers touched one another. Next, allowing for a clearance of 0.001 inch between each roller, the actual diameter of the shaft would be

$$1.0314 + \frac{16 \times 0.001}{3.1416} = 1.0365 \text{ inches}$$

The amount of clearance should depend, of course, upon the size of the rollers, the speed at which roll *E* revolves, and the kind of lubricant used.

To make possible the use of a chuck similar to that shown in Fig. 3 on any spinning lathe, an adapter of the type illustrated in Fig. 4 should be furnished for each lathe. The

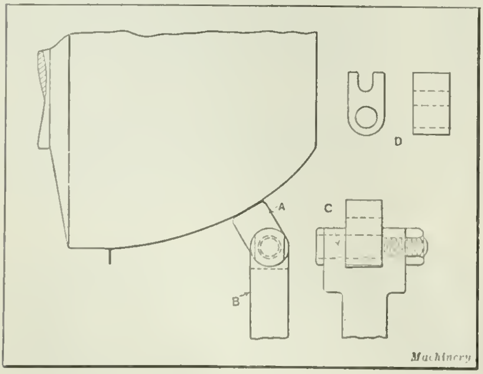


Fig. 1. Tool used for spinning Aluminum Shells

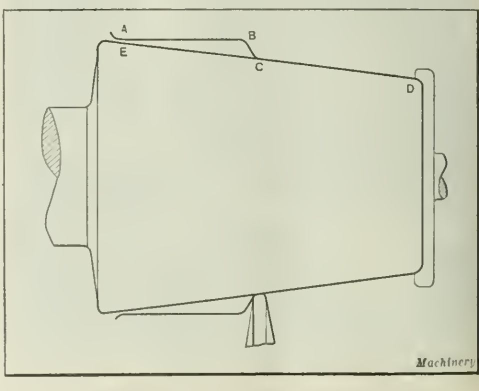

Fig. 2. Work that is partially shaped by Spinning

threads on the extending end of this adapter must agree with those in the head end of the chuck, while the threads in the tapped hole in the adapter should be made to suit those on the machine spindle. By increasing the length of the internally threaded end, the adapter may serve as an extension member.

Spinning Aluminum Shells

The tooling outfit just described is suitable for use in connection with steel shells only. The tools for shells made of aluminum or other soft metals are similar to those for steel shells so far as the chuck and tail-piece are concerned, but the spinning is done with a shoe instead of a roll. An idea of the way in which the operation is accomplished will be obtained by referring to Fig. 1. Shoe *A* is made of tool steel, and hardened. It is held in the jaws of the steel forging *B* by stud *C*. This stud allows the flat end of the shoe to remain tangent to the work at all times. At *D* is illustrated a shoe of recent development that is used on shells polished at some later stage. The first prong or tooth on the shoe that makes contact with the work smooths out the wrinkles, while the second, coming in contact with a comparatively smooth surface, acts as a burnisher.

Completing the Shape of Shells by Spinning

Fig. 2 shows how spinning may be done on water pails or other shells having the open end larger in diameter than the closed end. In drawing a long taper shell of this class it is often necessary to finish the shell partly in one of the operations, perhaps the third or fourth, and then completely finish it in another. The shell, when partly drawn, may follow the outline *ABCD*, and when it is finally drawn the outline may be as shown at *ED*. A shell of this type will wrinkle no matter how carefully the different drawing steps are proportioned, and therefore must be spun. If the preliminary and intermediate draws are so proportioned that the step *BC* is not more than about ½ inch high it is possible to eliminate the final draw by spinning the cylindrical part near the open end to the desired shape and dimensions after the wrinkles in the lower part of the shell have been smoothed out. This method not only eliminates the time required for an additional draw, but also saves the cost of a set of drawing dies.

In spinning to develop shapes that cannot be drawn readily or at a reasonable cost, the work is generally of the type that is larger in diameter at the bottom, or some place intermediate between the bottom and the open end, than at the open end. One way of spinning such work is from the inside, in which case the operation really consists of stretching the metal. However, the general principles of spinning apply in these instances as well. Inside spinning is often resorted to when the difference between the largest and smallest diameters of the finished work is too large to enable spinning to be done from the outside. The shell is then drawn to a diameter about midway between the two extremes, and one section is spun from the outside while the other is spun from the inside.

Example of Inside Spinning

An arrangement of tools for the inside spinning of the lower part of a steel pitcher is shown in Fig. 5. The shell is held in an internal chuck *A* by a tail-piece *B*. The spinning is done by a small roll *D* mounted on a long stiff holder *E*. The holder is fastened to the top of the lathe carriage in the regular manner. Lubricant is supplied to the bushing of roll *D* through a hole drilled along the center of holder *E*, an oil-cup being located near the right-hand end of the holder. The work is shaped by spinning the metal against a large roll *F* mounted on a cast-iron bracket *G* at the front of the machine. The shaft of roll *F* is mounted in roller bearings. Bracket *G* is fastened to a stationary part of the lathe and should be doweled or tongued so that when it is removed it can readily be replaced in the proper position. This equipment can be used for a variety of shapes by simply changing roll *F*.

In designing tools of this class, care must be exercised to insure that there is sufficient space to permit roller *D* to be conveniently inserted and withdrawn from the work and to see that the roll is large enough to do the work efficiently. If the space allowed is too limited for the tool design described, one way of overcoming the difficulty is by using an arrangement similar to that shown at *X*. Here a plate *H* with a ball embedded in the center is substituted for the tail-piece *B*. One end of the offset holder *K* bears against this ball and holds plate *H* in place against the work, while the other end is connected to the tailstock spindle by a sleeve. With such an arrangement there is plenty of room to bring the

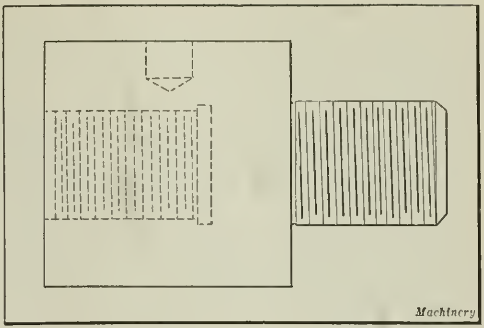

Fig. 4. Adapter which enables a Standard Chuck to be used on any Spinning Lathe

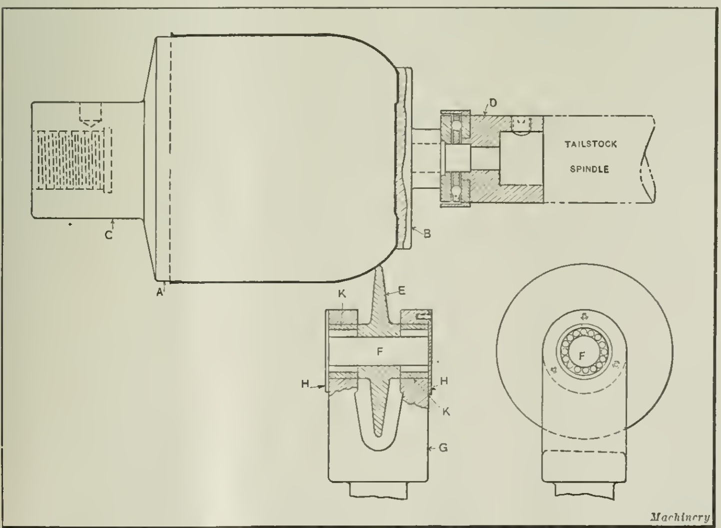

Fig. 3. Plain Tooling Equipment for removing the Wrinkles from Drawn Shells by Spinning

spinning roll against the inside of the work. The offset bar should be made of medium carbon steel and should be as heavy as possible; it should be hardened on the end bearing against the ball in plate *H*.

In using the tools in Fig. 5, roll *F* should be set up so that its axis will be parallel with that of chuck *A* and it should practically touch the chuck, as the slightest gap between the two members will cause pronounced marks on the finished work. This tooling is also intended for steel shells only. On aluminum work roll *F* will do more harm than good. For this reason the spinning of aluminum shells is performed without an outside support, the desired shape being produced by means of a cam. The screw in the cross-slide of the carriage is removed or released, and the slide linked rigidly to a roller or rollers traversing the guiding surface of the cam. As in the case of the roll bracket *G*, the member holding the form cam must be rigidly held to the machine, in such a way that an exact replacement is always possible.

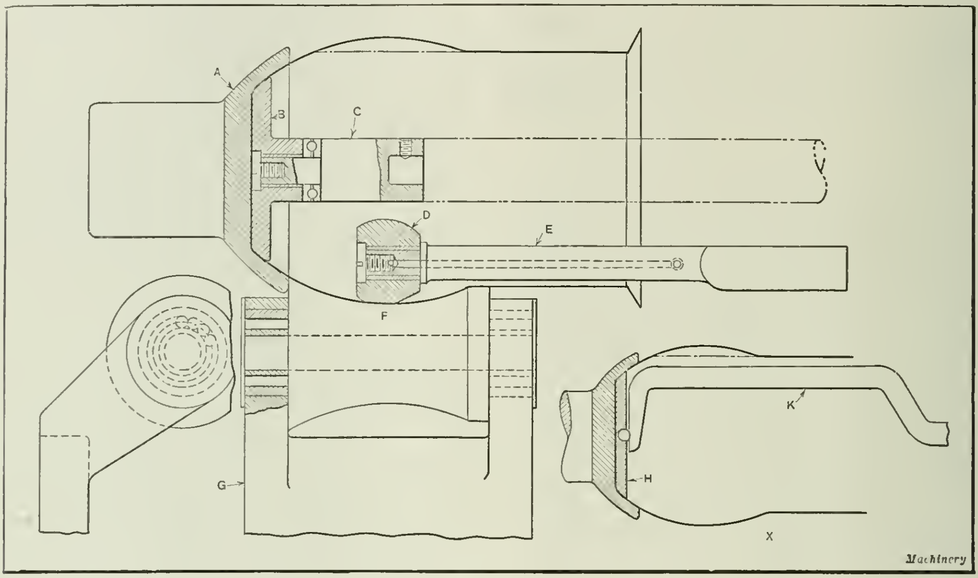

Fig. 5. Tooling Arrangement for Spinning the Lower Part of a Steel Pitcher from the Inside

Bulging the Open End of a Shell

Another application of internal spinning may be made in cases where one part of a shell is to be bulged out as shown in Fig. 6. It will be seen that the shell is held in a pot chuck *A*. The tail-piece has a live part *B* which revolves with the chuck, and a stationary part *C*, which is fastened to the tailstock spindle. A ball bearing *D* is placed between the live and stationary parts, and these two parts are held together by a screw that engages the threads of a tapped hole in the end of a stem on part *C*. The head of the screw seats against the end of the stem and allows part *B* to revolve freely on the stem.

The bulging is done by a roll *E* mounted on a crankshaft *F*, which is swiveled by means of handle *G*. The crankshaft and roller can be made to such dimensions that the work will be finished to the desired diameter when the highest point of the crank is brought directly toward the work, in which position an additional pressure on the handle will move the roll away from the work. On the other hand these parts could be so arranged that the entire throw of the crank is not utilized in producing a bulge of the desired diameter, but then it becomes necessary to provide an adjustable stop on part *C* for the handle to prevent too great a diameter of the bulged section. The first arrangement is more customary, as it enables a uniform product.

Different shapes and diameters of bulges can be formed by changing roll *E* to suit. The tail-piece *C* should be attached in such a manner to the tailstock spindle that convenient operation of handle *G* will be possible. A peculiarity found in work of this kind is that the open end of the shell becomes smaller in diameter after the bulging operation. This fact must be carefully considered in designing the tools.

Principle of True Spinning

Thus far the spinning tools described have been used for either smoothing out wrinkles or for stretching the metal, and while these operations may be classed under the general heading of "spinning," they are not true examples of spinning. The principle of true spinning is illustrated diagrammatically in Fig. 7. A cylindrical shell having the outline *ABCD* is required to be spun to the conical shape *EBCF*. To produce this shape, the spinning roll *H* is first pushed over the spinning chuck *I* along the line *BG* until a dent is made in the shell that resembles a saw tooth. The depth to which this dent can be made depends on a number of conditions, including the diameter of the shell after the final drawing operation, and the gage and quality of the metal from which the shell has been produced. A few trials will suffice to determine to what depth the dent should be made. When point *G* has been reached, the roll is traversed by means of the lathe carriage parallel to the center line of the work, that is, along line *GJ*.

After the work has been shaped along this line, the spinning roll is returned to point *G* and manipulated along line *GK* until another saw tooth has been produced, after which the roll is traversed along line *KL*. This process is repeated until the spinning roll reaches point *E*. Finally, the spinning roll is returned to point *B* and fed the entire distance along line *BE* in order to smooth the conical surface produced by the preceding steps. One of the absolute requirements of such work is that edge *A* of the shell rest slightly on the shank of the chuck so as to form a support while the first notch *BGM* is being formed. After that step there is a sufficient flange formed by the spinning to support the work firmly throughout the remainder of the operation.

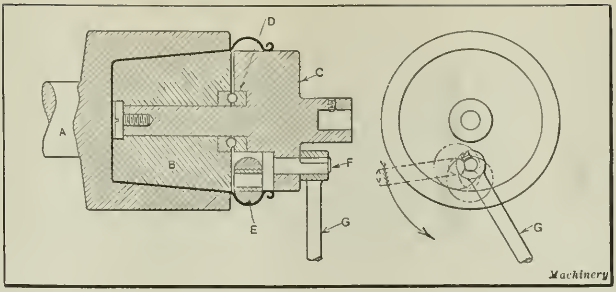

Fig. 6. Producing a Bulge near the Open End of a Drawn Shell

Fig. 8 illustrates the method of spinning a tapered shell intended for use as a coffee pot. The completed shell is represented by the heavy solid line and the preliminary shapes by the dotted lines. This method is known as "offset" spinning. Chuck *A* is made of 0.90 carbon steel and is formed to the shape of the finished part, with the diameter *BC* of the large end slightly smaller than the diameter of mouth *DE* of the work. The tailstock of the lathe is moved off center a distance *FG*, so as to be in line with the center of the shell when the latter is in contact with the front end of the spinning chuck. A plate *H*, ¼ or ⅜ inch thick, is placed at the bottom of the shell prior to mounting the shell on the chuck. This plate fills the bottom of the shell and forms a support over this entire end. The plate is made in two halves which have the corners *J* cut away to facilitate their removal from the shell after it has been spun down.

In order to have edge *K* of the shell supported by the shank of the chuck, the diameter of the chuck shank must be about the same as diameter *BC*. This is an instance in which a standardized chuck might not be convenient, at least not so far as the large diameter is concerned. The tail-plate *L* is of a standard type; it consists of an iron casting, held on a thrust bearing of the style shown in Fig. 3. When the difference between diameters *CM* and *DE* is a trifle larger than can be spun down successfully under average conditions, and when the quantity of work warrants it, the spinning operation may be facilitated by a preliminary shaping of the work, as shown at *N*, with an expanding die. Shells from 4 to 6 inches in diameter, when annealed after the final draw, can be expanded about ½ inch on a side or 1 inch in diameter without difficulty.

"Hot" Offset Spinning

A modification of offset spinning is "hot" offset spinning; this method is resorted to when the difference between the largest and smallest diameters of the finished work is great, and the length of the shell comparatively short. Fig. 10 shows this method applied to the spinning of a large steel tea kettle, and it will be seen that it is quite similar to the method shown in Fig. 8. In this case, however, a semicircular gas burner *A* has been added to the equipment. This burner is made of cast iron. It is about 2 inches deep radially and of a width to suit the work. The interior is cast hollow to form a chamber for the gas and air, which is admitted through a 1¼-inch pipe screwed into the tapped hole *B*. The face of the burner next to the shell is practically covered with holes 3/64 inch in diameter, spaced from ⅜ to ½ inch apart. The inside radius of the burner should be about 1 inch larger than the outside radius of the drawn shell.

The chuck is made in four parts, shank *C* being made of machine steel and the forming end *D* of 0.90 per cent carbon steel. End *D* is made hollow so that it will not conduct the heat away from the shell too rapidly; this construction also reduces the weight hanging on the connecting stud *E*. Stud *E* cannot be hardened, and so is made of a high-grade tough steel. The end cover *F* is also made of carbon steel. Both cover *F* and plate *H* can be replaced as they become worn, but the cover can be shimmed up and refaced a number of times before replacement is necessary.

The method of attaching the burner on the spinning lathe is represented diagrammatically in Fig. 11. The burner is held on bar *A*, which, in turn, is fastened to a horizontal rod supported in bearings *B* close to the floor. A foot-lever *C* and a second lever having a counterweight *D* are mounted on this horizontal rod. The air and gas lines are brought close to the burner, and are connected to it through flexible hose. Shut-off cocks are placed in a convenient position for the operator.

While the operator is placing a shell on the chuck, the burner is held in the position indicated by the dot-and-dash lines by the action of counterweight *D*. When he has finished putting the shell in place, he brings the burner into the working position by depressing foot-lever *C* and securing it under a hook fastened to the floor; this counteracts the tendency of weight *D* to swivel the horizontal rod. The gas and air are then turned on sufficiently to produce a good blue flame. After revolving the work a short time, it becomes red-hot and remains so until the flame is turned off at the end of the operation. The final smoothing-out touches are given to the work after it is again cold.

The limiting factor of hot offset spinning is the difference between the maximum and minimum diameters of the fin-

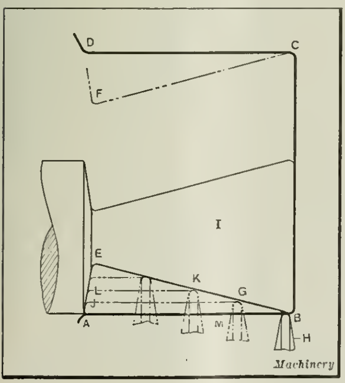

Fig. 7. Principle of True Spinning

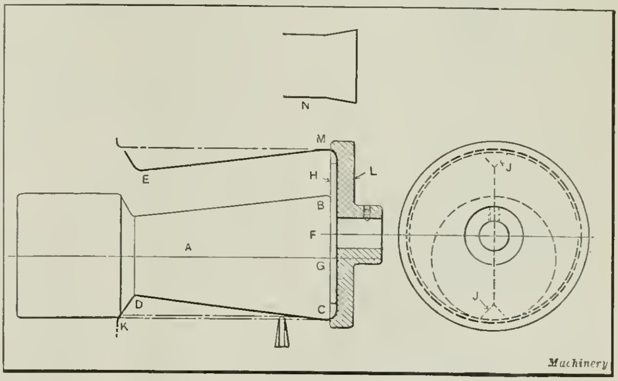

Fig. 8. Arrangement employed for an "Offset" Spinning Operation

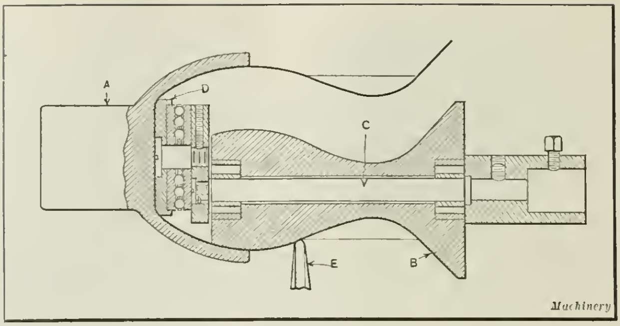

Fig. 9. Spinning a Pitcher by supporting the Form Roll on the Tailstock

ished part. Since the largest diameter of the chuck member *D*, Fig. 10, must be slightly smaller than the smallest diameter of the finished work, and its shape must be similar, it is obvious that if the difference in the diameters mentioned is great, the diameter of stud *E* may be so small that the stud will not have sufficient strength to sustain the job. The smallest diameter of neck that has been found in practice to give satisfactory results is about 1 inch.

Supporting Spinning Form by Tailstock Spindle

Another offset spinning operation is shown in Fig 9. This differs from the others that have been dealt with in that the spinning form is mounted on the tailstock spindle. The headstock spindle is again utilized for driving the shell through chuck *A*. This operation is the second one performed on the water pitcher, the first operation on which was shown in Fig. 5. Tools of the type used in Fig. 9 are employed when the shell is rather long, and consequently the driving means must be positive. The details of construction were decided upon after many trials and tests. The chuck is made of cast iron and the form roll *B* of chrome-nickel steel. The roll is provided at each end of its bore with a roller bearing, the inner race of which seats on the round bar *C*. On the left-hand end of this bar is mounted a member that supports a ball bearing having three circles of balls, so that the revolving work and tail-piece *D* have no effect on the supporting arrangement. The spinning operation, of course, is accomplished by the spinning roll *E*.

* * *

SAVINGS BY RECLAIMING SCRAP

In June MACHINERY an article appeared on the savings made possible by reclaiming a railroad scrap pile. Such reclamation work has proved to bring about considerable savings in other shops as well. The savings naturally vary with the prices of new material. In 1920, when new materials were at peak prices, the savings were the greatest. At the present time, when prices of new materials are considerably reduced, the percentage of savings is evidently much less; nevertheless, a material saving can be obtained by a careful study of the possibilities of reclaiming scrap. When prices were at their peak, the savings in some cases amounted to as much as 75 per cent of the cost of new equipment. In other cases the savings would be only from 15 to 30 per cent, according to the character of the reclaimed article. A material saving as a rule, can be made in the reclaiming of couplings and nipples, where the cost of new material would be comparatively high but the reclaiming cost almost nominal. Hand-trucks, wheelbarrows, and wrenches also present good opportunities for savings by reclaiming. The same is true of couplers, brake-beams, and springs. The important point to observe is to study the cost incident to reclaiming the article, so that more is not spent in trying to save the article than would be involved in the buying of a new part or tool. This mistake is frequently made, and in that case the apparent saving is turned into an item of expense.

RUSTLESS IRON

A material known as rustless iron, which is said to be suitable for machine construction, has been developed by J. J. Saville & Co., Ltd., Sheffield, England. This rustless iron can be bent cold to an angle of 180 degrees without fracture. The metal is said to take a polish equal to that obtained on electroplated surfaces, and to resist rust or tarnishing without any further attention. It is pointed out that it may be useful for machine tool parts, which by reason of their contact with cutting compounds are subject to corrosion. The material can be cold-worked by stamping, pressing, rolling, drawing or spinning, and can also be drop-forged. The physical properties of the metal are said to be as follows: Tensile strength, 80,000 pounds per square inch; elongation, 25 per cent in two inches; reduction of area, 60 per cent; and a hardness on the Brinell scale equal to 150.

QUALITY AND COST OF RAILROAD REPAIRS

By WARREN ICHLER

Does the quality and cost of repair work turned out in the roundhouse and the railroad main repair shop today compare favorably with that of former years? It would be extremely difficult, if not impossible, to answer this question with a plain yes or no. The writer, himself a railroad machinist asks the question not so much as an introduction to his own opinions, as to invite the expression of opinions from others who are interested in railroad repair work. If this question were asked at any gathering of railway mechanical officials, both affirmative and negative replies would doubtless be received. The affirmative replies might be expected mainly from the younger officials, who would naturally point out the high mileage and great tonnage records of modern locomotives as a proof of their assertion. Officials inclined to take the negative side of the question would probably cite the increased cost of roundhouse repair work as a basis for their claims. A little study of these methods of comparison will serve to show the fallacies of both.

Comparison of Past and Present Operating Methods

It is probably true that locomotives are making mileage and tonnage records today that are far beyond those achieved ten or twenty years ago; but the present-day locomotive is much better designed and runs over heavier and better rails and bridges than did its predecessors. Grading and ballasting have also been tamped more solidly each day by the heavy traffic. Then again, the locomotive generally receives more attention as regards feed-water treatment than was usual in the earlier days, and it is subject to more rigid inspection rules than it was twenty years ago.

Now, on the other side of the case, we cannot overlook the increasing cost of roundhouse or running repairs between successive shoppings of a locomotive, or general overhaulings of the boiler and machinery. At first thought it would appear that rising repair costs in the roundhouse are an indication of poorer work in the main repair shops, but this is not always true. The more rigid inspections already referred to would tend to increase greatly roundhouse maintenance costs. The fluctuations in the cost of labor and material are factors tending to disturb the uniformity of locomotive maintenance cost, and the "pooling" of engines might also be cited as a practice tending to send the cost of runing repairs skyrocketing. For the benefit of those who may be unfamiliar with this system of engine assignment, it might be noted that under this practice, all engines in freight or switching service are operated on the "first ready, first to go" principle, as distinguished from past practice, where each engine was assigned to a particular engineer and fireman.

This is cited as a cause of high maintenance cost, as it encourages the careless engineman to pass his errors of omission in the matter of lubrication, inspection, etc., on to other shoulders. Where responsibility can thus be shifted, a good deal of minor repair work is neglected, until finally more serious trouble results from this neglect and the engine has to be removed from service to receive so-called "heavy roundhouse repairs," which are of necessity more costly than similar work done in the regular repair shops provided with better facilities.

In an effort to find some reliable means of comparing present-day repair work with that of twenty years past, the writer studied the matter on what might be called a "job for job" basis; that is, the method of handling each special repair job on a locomotive in 1904 was compared with the way such work was handled in 1922. In comparing present-day methods with those of the past, the writer has carefully selected examples that have come within his close personal observation. Only a few of the major operations involved in repairing a locomotive can be dealt with in a short article, but the ones selected are representative of common practice.

Counterbalancing Methods

The problem of counterbalancing naturally comes first as a basic matter in repairing or overhauling locomotives. By "counterbalancing" is meant the adding of weights to one side of a driving wheel to balance the weight of the side-rods, crankpins, and a portion of the reciprocating parts. Everyone is familiar with the solid segment of metal seen on locomotive driving wheels opposite the crankpin, and it is in this segment that the balancing weight is secured. Weight is added or subtracted from this segment, according to certain well-established formulas of design, by changing the volume of the lead cores. It was formerly common practice to test the static balancing of the driving wheels each time the locomotive was shopped for a general overhauling. Today this is rarely done, except when new driving wheel centers are applied. It is still the practice of one large western railway, however, to have the counterbalancing of every engine tested at each shop, but to the writer's knowledge, this is the only instance where this practice is adhered to. A somewhat extended inquiry into this subject served to verify this statement.

Setting Axles Parallel

Another fundamental operation in repairing locomotives is the adjusting of the shoes and wedges to insure parallelism of the driving axles, and to set the driving axles perpendicular to the longitudinal center line of the engine and track. The laying out, planing, and adjusting of these castings and their accessories, call for a high degree of skill, and in former years an error of 1/32 inch in the parallelism of the driving axles after the locomotive was remounted on its wheels, was deemed sufficient to justify a readjustment of the shoes and wedges, whereas an error of 1/16 inch receives scant attention in most shops at present. It may be noted here that the error in perpendicularity to the center line of the tracks generally causes rapid cutting or wearing of the driving wheel tires, while an error in counterbalancing is shown in the riding qualities of the engine and the rapid wear of the side-rod bushings or bearings.

Eliminating Needless Refinements

The writer has purposely refrained from mentioning such operations as the repairing of links and other valve motion parts where the old-time machinist gasps in horror over the present-day practices of peening, wedging, stretching, and twisting the various parts to the semblance of fits, instead of carefully fitting and polishing such parts. This omission is not referred to with the desire to sanction present-day practices or to deride the methods formerly employed. Doubtless many of these refinements were useless. A high polish on non-bearing surfaces never pulled an extra pound of freight a foot, and in many instances a good coat of paint would have served the purpose quite as well as a polished surface. However, somewhere between the extremes of the apparent carelessness of the present and the two expensive carefulness of the past, there must be a middle course which could be adopted, and undoubtedly some railroads are already following such a course.

The writer believes that the quality of repair work on locomotives has deteriorated in certain branches where it should not have been allowed to, and on the other hand there are some cases in which the elimination of needless time-consuming refinements have been a great advantage. With the rapid development of locomotives it is not to be expected that a progressive railroad official would feel it wise to spend large sums in costly repairs and refinements on his older equipment, when it may soon be retired from service. If, however, a clearly defined policy of lengthening the life of present equipment is decided upon, it is probable that there will be a return to the slower and more careful methods of previous years in handling certain classes of work. In fact, from the viewpoint of economy and good mechanical practice, such a course would prove necessary.

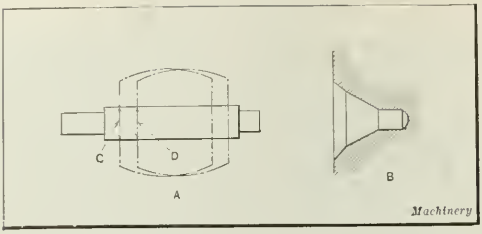

Fig. 1. (A) Diagram illustrating Extreme Positions a Part may occupy on an Arbor; (B) Economical Method of making Centers

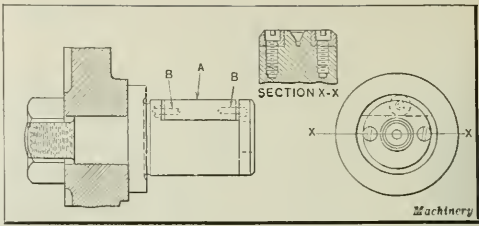

Fig. 2. Quick-acting Type of Arbor on which the Work is securely clamped in Place by Means of a Roller

DESIGN OF WORK-HOLDING ARBORS

By H. P. LOSELY, Industrial Engineer, Detroit, Mich.

Work-holding arbors are generally tapered 0.006 inch in diameter per foot of length, this amount permitting the piece to be held satisfactorily without requiring an excessive pressure to force it on the arbor, thus eliminating distortion and misalignment of the work. The amount of taper may be increased when there is no great demand for accuracy. In designing an arbor for a special job, attention should be given to the maximum and minimum diameters allowed for the hole in the work at the time the latter is to be put on the arbor. The points along the length of the arbor at which the work will be a pressed fit should also be calculated. In Fig. 1 at *A* the two points between which the left end of the work will always be located are indicated by dimensions *C* and *D*. Care should be taken to make the arbor long enough so that it will accommodate the piece in either of the two extreme positions.

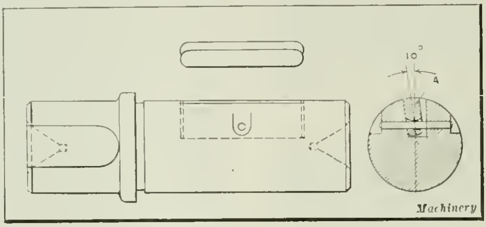

Fig. 3. Another Quick-acting Arbor having a Swiveling Leaf for clamping the Work

In order that the large end of the arbor may be readily distinguished, it is customary to make the turned down portion at this end longer than at the small end and also to provide a flat on the large end for the set-screw of the lathe dog. The ends of the arbor should be hardened, and the centers in the ends lapped to fit 60-degree lathe centers. It is customary to counterbore each center in order to prevent the edge from being damaged; this is more economically accomplished by countersinking with a 90-degree countersink as illustrated at *B*, Fig. 1, or with a center drill. If the tolerance on the work is large, or if it is desired to bring each piece into the same longitudinal position on the arbor on account of the setting of tools on the machine, a properly designed expanding arbor should be employed. Some excellent examples of expanding arbors are given in the chapter on arbors in a book entitled "Tools, Chucks and Fixtures," published by MACHINERY.

Types of quick-acting arbors which are very useful for facing operations are illustrated in Figs. 2 and 3. With the arbor shown in Fig. 2, the work is slipped on and then turned backward a slight amount, the result being that roller *A* is given a slight movement permitted by the size of the holes in which the outer ends of pins *B* are contained. This movement of the roller causes the work to be clamped securely in place. The tool is then fed in, and when finished the blank can be quickly pulled off.

Leaf *A*, Fig. 3, functions similarly to roller *A*, Fig. 2. The leaf in Fig. 3 should be ground while in the position shown. It is, of course, evident that in each case the clamping action of the roller or leaf forces the work into a slightly eccentric position, and therefore this type of arbor can only be used for facing or roughing operations. The arbors are also limited to work where the cut is continuous, as an intermittent release of the cutting pressure, such as occurs in facing gears, is liable to release the roller or leaf and allow the arbor to turn free in the part. However, in their limited field these arbors are great time-savers, being particularly suitable for such work as the facing of gear blanks.

Knock-off arbors for threaded parts are shown in Figs. 4 and 5. The one shown in Fig. 4 is of a common type, collar *A* being provided with lugs to facilitate its rotation relative to the arbor, when an operation has been completed. The collar on the arbor in Fig. 5 is provided with a flange having two recesses instead of the customary lugs. This is a safety feature, which has been adopted to reduce the likelihood of injury to an operator.

* * *

The total number of motor vehicles in France increased from about 100 000 in 1913 to 208,000 in 1921. Of these 93,000 are commercial vehicles. The number of commercial vehicles in 1913 was only 8000.

Grinding Wheel Nomenclature

By H. A. PLUSCH, Plant Manager, Precision Grinding Wheel Co., Inc., Philadelphia, Pa.

Only two groups of artificial abrasives are used in the production of grinding wheels—aluminum oxide and silicon carbide—but different trade names have been adopted by individual manufacturers to distinguish their products from others. This practice has resulted in much confusion among grinding wheel users. The present article points out to which of the two groups well-known makes of grinding wheels belong, and explains the meaning of terms that are commonly used by ceramic engineers, but that are not always clear to the grinding-wheel user.

GRINDING wheel nomenclature is a source of perplexity to many users of grinding wheels who are not familiar with the processes followed in their manufacture. This confusion, to a large extent, is due to the fact that different trade names are used for wheels made from the same class of abrasive and the same or different symbols are employed to designate wheels of supposedly the same grade. Grinding wheels are made from both natural and artificial abrasives, the chief natural abrasives being emery and corundum. The value of the natural abrasives depends upon the percentage of crystalline aluminum oxide which they contain. Emery has a large percentage of non-cutting elements, and for that reason is used comparatively little in machine grinding. This abrasive in its natural state is in a crystalline form, whereas artificial or synthetic emery (aluminous abrasive) is crystallized in the electric arc furnace.

Artificial Abrasives

Artificial abrasives are produced in electric furnaces either from bauxite or from a mixture of coke, sand, salt, and sawdust, of which the chief constituents are coke and sand. Bauxite is a soft earth, and is the purest form of aluminum oxide found in nature. The oxide crystallizes when bauxite is fused in the electric arc furnace, and because of the abrasive being artificially produced, undesirable elements can be eliminated. It is due to this fact that artificial abrasive wheels have become popular.

Crystalline aluminum oxide ranges in color from white to deep wine color. Wheels made from this abrasive are recommended for grinding materials having a high tensile strength, including the various steels, annealed malleable iron, wrought iron, tough bronzes and tungsten. The trade name "Hy-Tens" given to wheels of this class manufactured by the Precision Grinding Wheel Co., Inc., conveys an idea of the materials that the wheels are intended for. Aluminum oxide grains are hard, tough, and dense, and when fractured leave sharp cutting edges.

The abrasive produced from the coke and sand mixture is known as silicon carbide, and ranges in color from green to a bluish black. The electric resistance furnace is used in its production. Wheels made from this abrasive are more efficient for grinding materials of low tensile strength, such as soft brasses and bronzes, cast and chilled iron, aluminum, copper, marble, granite, leather, and other non-metallic substances. The trade name "Lo-Tens" has been given to silicon-carbide wheels manufactured by the Precision Grinding Wheel Co., Inc. The accompanying table lists the names given by various companies to the aluminum-oxide and silicon-carbide grinding wheels of their manufacture. Silicon carbide is the harder of the two abrasives, but it is quite brittle.

TRADE NAMES GIVEN TO ARTIFICIAL ABRASIVES USED IN THE MANUFACTURE OF GRINDING WHEELS

Manufacturers	Aluminum-Oxide Abrasives	Silicon-Carbide Abrasives
Abrasive Co.	Borolon	Electrolon
American Emery Wheel Works	Corundum	Carbolite
Bridgeport Safety Emery Wheel Co.	Carbo-Alumina	Silexon
Carborundum Co.	Aloxite	Carborundum
Cortland Grinding Wheels Corporation	Oxaluma	Carbora
Detroit-Star Grinding Wheel Co.	Staralox	Staralon
Maxf Grinding Wheel Corp.	Sapphite	Carbo
Norton Co.	Alundum	Crystolon
Precision Grinding Wheel Co., Inc.	Hy-Tens	Lo-Tens
Safety Emery Wheel Co.	Rex	Corex
Sterling Grinding Wheel Co.	Sterlith	Sterbon
Vitrified Wheel Co.	Borofied	Carbofied
Waltham Grinding Wheel Co.	Alowalt	Carbowalt

Machinery

Bonding Processes

The color of both aluminum-oxide and silicon-carbide grinding wheels depends on the material used to hold the abrasive particles together, which is termed the "bond." The exact shade, however, is likely to vary somewhat with wheels of the same bond that are produced in the same heat, and so a slight variation in the shade of two wheels does not necessarily indicate a difference in grade. The four most important bonding processes are known as the vitrified, silicate, elastic, and rubber processes, and these names are applied to the grinding wheels produced by them. The use of different bonds permits the manufacture of wheels of different characteristics to suit all classes of grinding. Vitrified wheels are standard for most grinding operations, the other kinds being used when special conditions are encountered. Probably 80 per cent of all grinding wheels are vitrified. The bond used in this process consists of mineral and clay mixtures, which are fused at a high temperature, either to a glass or a vitrified matrix.

Silicate wheels are bonded by a mixture of minerals and silicate of soda or water glass, and baked at comparatively low temperatures. The wheels made by this process are also known as semi-vitrified. They are superior for tool and similar grinding where only a small amount of material is removed. On account of generating less heat, the danger of drawing the temper from a tool is minimized. Elastic wheels are bonded with shellac and other ingredients, and baked at low temperatures. Wheels made by this process have considerable elasticity, and are suitable where thin wheels are required, or where a high finish is necessary.

Rubber wheels are bonded with special mixtures of rubber, and then vulcanized. Wheels of this class have substantially the same advantages as elastic wheels, except that they can be made harder and thinner to meet more severe conditions. Both elastic and vulcanized wheels are used for cutting off tubing, wire, thin sheets of steel or brass, and parts which are difficult to hold while cutting off with the commonly used tools.

Vitrified wheels can be readily distinguished from the other wheels by their reddish or reddish-brown color, and the clean ringing sound which results when they are tapped. Silicate wheels are easily recognized by their light gray color. Elastic and vulcanized wheels are almost black, but they may be distinguished by their odor when subjected to the friction of a grinding operation or when a small part is burned. Elastic wheels emit an aroma, whereas rubber wheels give off the odor of burning rubber.

The grain or coarseness of a wheel refers to the size of the abrasive particles used in making the wheel. It is designated by the number of meshes to the linear inch through which the abrasive will pass. For instance, a 24-grain wheel is one made from an abrasive which will pass through a sieve having twenty-four meshes to the linear inch. Wheels may be made with the abrasive particles all one size or a combination of sizes. In designating a combination-grain wheel, some manufacturers use special numbers which represent the average grain size, and others give a number indicating the coarsest grain.

The term "grade" refers to the strength of the bond, or the tenacity with which it holds the abrasive particles in the body of the wheel while subjected to grinding pressure. The term has no reference to the hardness of the particles themselves. The grade is determined by pressing the beveled blade of a chisel-like hand tool into the side of the wheel and then giving the tool a turn or twist. The resistence to this twist indicates the grade of the wheel.

The grades range from extra soft to special extra hard. A soft grade designates a bond that breaks down rapidly in the grinding operation, and a hard grade, a bond that has a stronger hold on the abrasive particles. Letters of the alphabet and numbers, or a combination of both, are used for denoting the grade of wheels. Many manufacturers use the letter M to designate a medium-grade wheel, and preceding or succeeding letters to distinguish softer or harder wheels. While every manufacturer's grade M wheel is about the same, an allowance should be made for variations in manufacture. Different grinding results are often obtained by wheels of the same grade but different manufacture.

WIRE-TWISTING FIXTURE

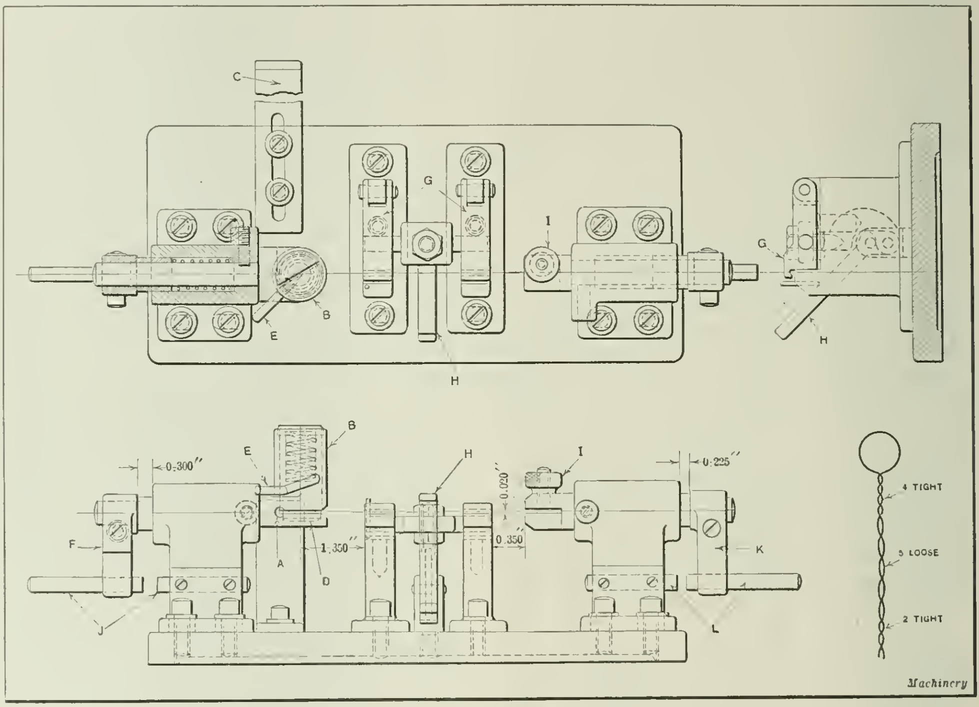
By D. A. NEVIN

The accompanying illustration shows a fixture which may be used for twisting wire into various shapes. The design may be arranged for any desired length or number of twists to suit the requirements. The work (shown in the lower right-hand corner) is made from 0.030-inch diameter copper wire which has four tight turns at the loop end, two tight turns at the opposite end, and five loose turns in the center.

The wire is passed through hole *A* of the fixture, and the length gaged by the adjustable stop *C* at the rear. The middle portion is then looped around the stud *D*, which operates in post *B*, so that when pin *E* is turned in the cam-slot from which it projects, the stud will be raised sufficiently to permit the looped wire to be removed through the slot in the lower part of post *B*, which is an integral part of the spindle to which the crank-arm *F* is attached.

The wire, after being looped as described, is then swung around so that it may be secured by the hinged clamps *G* that operate in unison through the medium of the handle *H*, the manipulation of which actuates a link mechanism. The ends of the wire are secured in a clamp in the footstock by means of the knurled nut *I*.

In making the piece shown in the illustration, the fixture is operated in the following manner: First the crank *F* in the headstock is turned to the right four turns, and then the stop-pins *J* are adjusted to engage at this point. This produces the four tight twists next to the loop. Then the crank *K* in the footstock is rotated twice, also to the right, to produce the twists in this end of the work. The stop-pins *L* are not adjusted at this time, however, for the five loose turns must first be made before these pins are set. The clamps *G* are next released so that the five loose twists may be made by turning the crank *K*. At the completion of this operation the stop-pins *L* are set. A fixture of this kind may be operated with speed after a little practice.



Fixture for twisting Wire by Hand to form Piece shown in Lower Right-hand Corner

Fig. 1. Battery of Power Forcing Presses used in broaching Motor Stators

Broaching Stators on Forcing Presses

THE hole in assembled stators for electric motors is finished in the General Electric Co.'s plant at Rochester, N. Y., by broaching on Lucas power forcing presses, and the production obtained on this job is 550 stators for one operator per eight-hour day. For handling this work a battery of six of these presses is employed, as shown in Fig. 1.

A detail of the assembled stator showing the size of the broached hole is illustrated in Fig. 4. It will be noticed that the hole is held to a tolerance of 0.002 inch on the diameter. A close-up view of one of the presses set up for this operation is shown in Fig. 2, and the details of the section broach used may be seen by referring to the illustration Fig. 3.

The broach is made in seven sections, each having straight teeth, and these sections are assembled on a stem, which is screwed into the shank of the tool. The broach sections are held in place by a collar at the end, which acts as a pilot when the tool is in use. It has been found in this case that the straight-toothed broach gives more satisfactory results than a broach made of spiral-tooth sections, both of which have been tried on this job. After the broaching sections have been assembled, they are ground to a taper of 0.033 inch, starting with the second section from the end and extending to the last few teeth in the section nearest the shank, which have no taper. The design of this tool is such that in enlarging the diameter of the hole approximately 0.026 inch, each tooth takes a cut of about 0.001 inch. The broach is held in the spindle of the machine by means of a pin passing through the shouldered end, so that it may be removed, as is frequently necessary during the course of a day's work. Referring to Fig. 2, it will be seen that the fixture on which the stator is located is set on ground parallels which bring the face of the stator at right angles to the travel of the broach so that a true hole will be obtained. The fixture is counterbored to a slight depth on the top to accommodate the heads of the rivets by which the stator stampings are assembled.

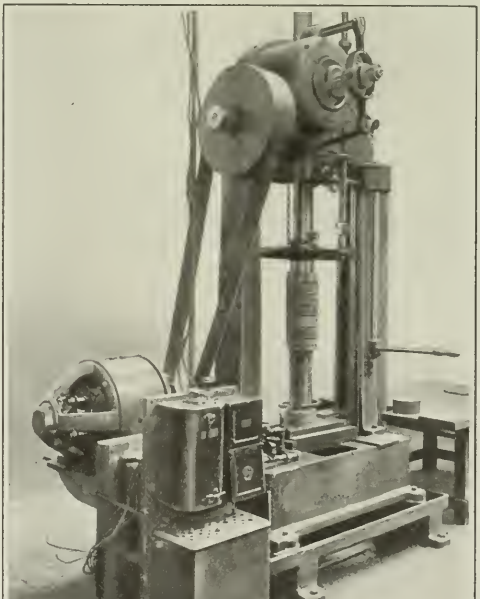


Fig. 2. Set-up of Forcing Press, showing Work and Broach

As the broach enters the stator it is guided by the pilot, and while it is passing through, the stator is advanced on the shank of the broach. This continues until the entire shank is loaded to capacity, as shown in the illustration. When eight stators are on the shank of the tool, the pin that secures the broach to the machine spindle is knocked out and the work

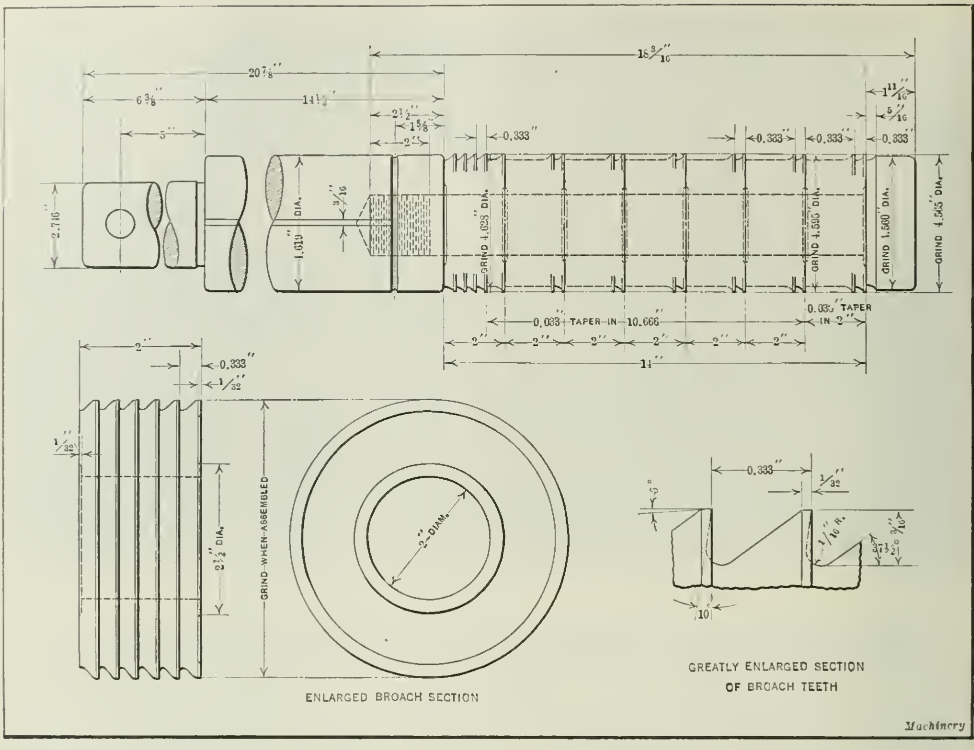

Fig. 3. Broach made in Sections, which is used in finishing the Holes in Stators

slipped off the end of the broach, after which the tool is again ready for use. It is of vital importance that the hole be broached square with the face of the assembled stator, as otherwise the outside diameter would not clean up when subsequently turned. The turning operation is performed on an Adams "Short-cut" lathe, and the work is held by air chucks.

The forcing presses are driven by a 10-horsepower motor which runs at a speed of 1150 revolutions per minute. The tool is lubricated and the chips washed from the teeth by two pipe coils, one above and one below the bolster plate of the machine. The inside of these coils is perforated so that a stream of cutting compound will be delivered to the teeth from above and the accumulated chips washed from the teeth beneath the work-holding jig after the broach has passed through.

These presses are of thirty-ton capacity, and there is a working space of 48 inches between the fixture and the end of the spindle in which the broach is fastened. Under the conditions stated, the broach will give good service for a week or ten days before it is necessary to regrind the teeth. As the larger sections are ground down and become too small for use in the same position on the tool, they are successively moved nearer the pilot end until they become too small for further use.

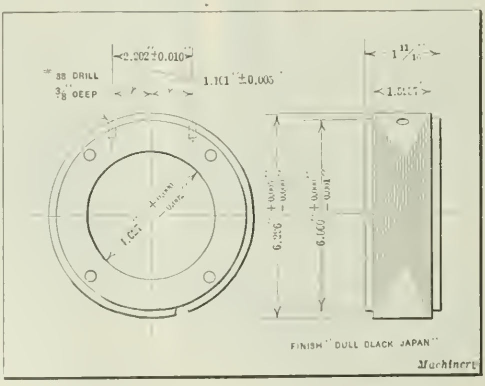

Fig. 4. Stator broached on Forcing Presses

AUSTRALIAN MACHINERY MARKET

The machinery market of Australia is dominated by the United Kingdom and the United States. Of the total imports in 1913, amounting to approximately $21,000,000, about $6,000,000 or 29 per cent came from the United States. By 1921 this had increased to about $16,000,000 or 43 per cent of the total, which was then $37,000,000.

German goods, excluded by Australian war-time legislation, may enter the field again next August. In 1913 machinery imports from Germany reached nearly $2,000,000 or 9 per cent of the total.

The growth in imports from the United States is remarkable in view of the advantages that are enjoyed in the Australian market by the United Kingdom, among which are: (1) substantially heavy preferential tariffs; (2) favorable exchange rates; (3) close political, commercial and financial affiliations. Many importing machinery dealers have intimate connections with Great Britain, some of them actually being branches of British houses. Many Australian industrial establishments are financed by British capital. Three leading banks in Australia are British and the rest have branches in Great Britain, but no American bank has been established there as yet.

The Machine Tool Trade in Japan

By YAMATAKE & CO., Tokyo, Japan

JAPAN buys all classes of machine tools—lathes, turret lathes, milling and drilling machines, gear hobbers and shapers, horizontal boring machines, planers, shapers, slotters, grinders of every description, electric and pneumatic tools, and many special machines. Machines are purchased in all sizes, from the bench lathe to the heavy gun turning lathe, and other machine tools in similar proportion. It is easier to say what machine tools Japan is not buying as yet, that is, machines for quantity production. In this respect Japan is far behind the United States, England, and the more progressive continental countries. A few branches of the Japanese industry have begun to use automatic and other special machines for quantity production, but very few factories have a production large enough to warrant the expense of installing special machinery of this kind.

In woodworking machines the staple types of band, circular and gang saws, planers, etc., form the bulk of the business, although there is some trade in special machines for certain industries.

The Government is the Principal Buyer

The most important buyer is still the government (Army, Navy, State Railways, etc.). The electric, shipbuilding, and general machine-building industries also are large consumers of machine tools. Of course there are numerous other buyers, such as bicycle makers, repair shops of the big sugar, paper, and spinning mills, and many others. The automobile industry is still in its infancy and is likely to be of slow growth. High production cost, a small market and oppressive taxation militate against its success.

The imports of metal-working and woodworking machines in 1920 were valued at 13 650,000 yen (approximately $6,825,000). In addition there is a home industry which in that year produced machines to a value of nearly 10,000,000 yen. The figures for 1921 are not available yet, but doubtless are much below these figures. During the present year, both imports and home production have receded further, as the Government is buying little, and only a few of the private industries are prospering.

VALUE OF MACHINE TOOLS AND METAL-WORKING MACHINERY EXPORTED TO JAPAN IN 1921

Month	Lathes	Sharpening and Grinding Machines	Other Machine Tools	Total of Machine Tools	All Other Metal-working Machinery	Total of Machine Tools and Metal-working Machinery

Machinery

American and British Exports to Japan

In 1920 the United States sent to Japan 10,964,000 yen ($5,480,000), and Great Britain 2,573,000 yen ($1,280,000) worth of machine tools. Import from other countries were insignificant in 1920, but now imports from Germany are appearing on the market again.

Where machines made in the United States are preferred, the makers have won this distinction through modern design, high-class workmanship, and honesty; but many manufacturers in the United States have hurt their reputations in Japan through poor quality of their shipments and disregard of contracts in past boom times. This class of manufacturers will find it difficult to reconquer the market when conditions are better again.

British machines are sold a good deal through force of habit. They were the first in many factories and have given satisfaction; thus the repeat orders go to England, even where other countries can offer better machines. It must be acknowledged, however, that the British machine tool industry is less self-satisfied and more progressive now than it was before the war. When business revives, England will probably put up a good fight for a larger share of the imports. Germany will gradually gain third place in imports, but for several years will lag a long way behind her two big competitors.

Advice of American Manufacturers

In order for American manufacturers to obtain greater trade with Japan they should heed the following advice, which they have heard often but have not always heeded:

1. If you want to do export trade, stick to it. If you intend to engage in export business only as a stop-gap when times are bad in the United States, you will be disappointed and will hurt the reputation of other manufacturers who want to stay in the export trade and treat foreign customers accordingly.

2. Follow the instructions of your buyers minutely even if you do not understand their necessity.

3. Pack twice as carefully as you would do for the home trade. Consider that the packages may be stood upside down for a five-thousand mile trip, and will be thrown about. Will they stand it?

4. Have some *responsible* man check the packing list. Better have it checked twice. A missing tool or cam may make the machine useless for many months, until replaced. Remember that the foreign buyer cannot get your shipping department over the long distance telephone and say what he thinks about its delinquencies, but he remembers your neglect and in the end *you* pay for it in loss of business.

5. If the machine you are selling is complicated and if you are in the habit of sending a mechanic to install it properly for the buyer, consider the position of your foreign buyer who probably has never seen such a machine and has nobody to advise him. Put yourself in his place and work out detailed instructions for his benefit. The same thing will help a dozen foreign customers who would otherwise have trouble and be dissatisfied with your product. Have these instructions made by your technical staff and thoroughly tested by persons not familiar with the machine. The specialist generally omits the most important point since it is an old story to him; but it is one which the buyer does not know.

6. Half of the machines received from the United States arrive badly rusted. This is probably due to the fact that a cheap "export" slush is widely used although it is well known that the best rust-preventing slush is barely good enough to protect a machine coming to the East in the rainy season. The manufacturer hurts his interest dollars for every cent he saves in using cheap rust preventives on his export shipments.

Inspecting by Optical Projection

SCREW thread elements, gear teeth, cutter forms and in fact any profile or contour may be accurately inspected by the projection of an image on a screen. This principle of inspection has been incorporated in several instruments for laboratory and commercial inspection work. The advantages of this method of inspection are rapidity and accuracy. Optical inspection instruments contain mainly a source of light, a system of lenses, and a surface on which the image may be cast. The surface or object to be inspected is placed in the ray of light, usually between two lenses of the optical system. The surface on which the image is cast is often a chart containing a master outline with which the projected image may be compared. This method of comparing the accuracy of contours is largely used in inspecting screw threads.

The application of this system of inspection is limited only by the size of the work and the area of the screen or chart on which the image is projected. Provided the magnification is definitely known it is even practicable to measure the image direct, so that in the case of the pitch of a thread, errors can be determined in terms of actual measurement. Ordinarily, however, the optical projector is used as a comparator.

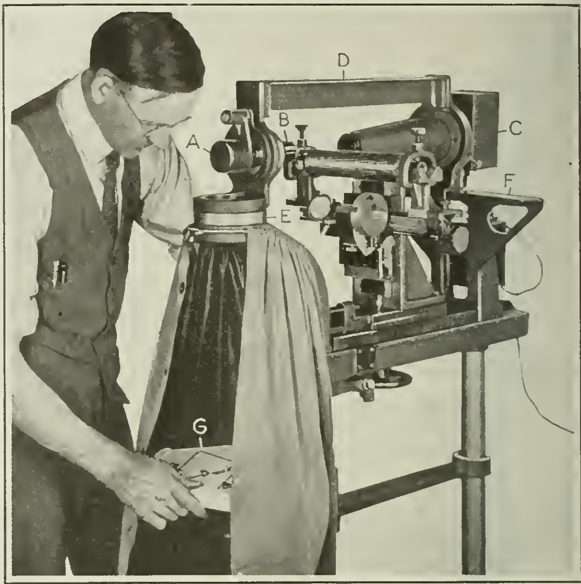

Fig. 1. Adjusting the Optical Instrument for inspecting a Large Screw Thread

During the war, the Bausch & Lomb Optical Co., Rochester, N. Y., developed an optical instrument which proved so satisfactory for the company's own use that it is now being commercially manufactured. It is stated that when using this instrument as a thread comparator it is possible to inspect five hundred screws per hour for external, pitch and root diameter, thread shape, evenness of outline, angle, and width of flat at top and root. This instrument is also used for testing gears to determine tooth form and contact and for a great variety of formed work. The machine differs in two particulars from others in commercial use—first, in the optical system, and second, in the arrangement and type of the thread chart.

General Construction of the Optical Projector

The stand on which the instrument is mounted is furnished with casters so that it may be moved easily from place to place in the shop or laboratory. A feature of the caster mountings is the leveling screw in each foot of the stand, by means of which the instrument may be leveled on an uneven floor. The projector does not require a darkroom, but may be operated successfully in any room, provided the image is not exposed to a direct ray of light, as from a window.

For ordinary sized work the image is projected on a chart which is part of the instrument, the position of which may be varied as required to increase the magnification. For this purpose the chart is attached to a holder. An arm on the holder has bearings on the two uprights of the stand so that the chart may be located vertically in any position. Besides using a chart for comparison, the holder is designed to accommodate a photographic plate holder as well, so that permanent records of the results may be obtained. The image is projected vertically downward to the chart or plate holder and a curtain is draped around it to exclude light and intensify the sharpness of the outline projected. The fact that the screen is part of the instrument itself prevents the vibration which is often a cause of much trouble where an independently supported screen is used.

The work-carrier consists of a compound slide which may be adjusted in three directions by means of handwheels to bring the work into proper position in the optical rays. The adjustment of the work within the field is the means for focussing the image on the screen. The source of light regularly used is a special concentrated single-filament, 6-volt, 108-watt Mazda lamp, which may be lighted by connecting it to a lamp socket. This lamp furnishes a steady illumination and is inexpensive to operate. For extremely careful work the "Tungsarc" lamp is recommended or where greater intensity of light is desirable, such as when projecting gear contours at high magnifications. An arc lamp, however, may cause difficulty in maintaining a steady illumination, due to fluctuations.

Fixed Optical System

The optical system used in the Bausch & Lomb projector is of special design and is shown diagrammatically in Fig. 3. The system is fixed—that is, the illuminating, reflecting, and magnifying units remain in fixed relation to each other and the image is sharply focussed by changing the position of the work in the field instead of by moving any of the optical system units. The source of light is graphically indicated at *A*, from which the rays pass through a condenser consisting of a special lens *B* and a supplementary condenser *C*.

The lens and the supplementary condenser are mounted in a long cone (see Figs. 1 and 2) which keeps them in permanent optical alignment. The lens is contained in a focussing mount by means of which it can be adjusted to direct the beam of light to the focal point of condenser *C*, Fig. 3. This causes a concentrated beam of parallel light rays to issue from the iris diaphragm *D* which is located directly in front of the condenser at the end of the cone. This diaphragm is for adjusting the diameter of the beam of light. The rays pass and intersect the outline to be inspected, the work being positioned within the field as at *E*, and the interrupted rays then pass through the objective lens *F* of a compound microscope.

Beyond the eye-piece *G* of the microscope there is a right-angle prism *H* which reflects the light down and casts the image on the chart or plate, as indicated at *I*. The prism is mounted in a holder *A*, Fig. 1, and may be swung out of the way if it is desired to project the light straight on a large screen instead of vertically downward. This is often necessary in the case of large work requiring high magnification. The compound microscope shown at *B*, is used in place of an ordinary projection lens, and in combination with the prism enables average work to be inspected with the screen or chart as a part of the machine. The advantage of this arrangement is clearly indicated in the illustrations. It also permits the machine to be no larger than would ordinarily be required for the optical system alone.

Selection of Lenses and Eye-pieces

As previously stated, focussing is accomplished by changing the position of the object, not by moving the lenses. The instrument is generally furnished with a 24-millimeter (focal length) objective lens contained in a long tapering mount of small diameter so that it may extend over the top of large diameter gages as shown in Fig. 1. A 48-millimeter objective lens is used where less magnification or a larger field at a greater projection distance is wanted. The eye-pieces regularly employed with these lenses are of 5 and 12.5 times magnification, respectively, and the combinations furnish a wide range of magnification. This equipment permits the projection of threads of 1/3 inch pitch or less and gears of 12 diametral pitch or finer. A chart giving the magnification when the chart holder is set at a specified distance from the prism and when certain combinations of these lenses and eye-pieces are used, is referred to when setting up the machine.

When a vertical screen is used separately from the instrument, as when projecting a large contour, special lenses are employed. These lenses replace the compound microscope which may be completely removed from the instrument and the prism swung aside to permit the projection of the image on the vertical screen. The supplementary condenser *C*, Fig. 3, is also removed together with the iris diaphragm *D*, and the illuminating beam of light is made parallel by the focussing movement of lens *B* which may be moved on a helix by a lever. In connection with the focussing of the lens *B*, the position of the lamp in its housing *C*, Fig. 1, must be adjusted until an image is properly formed on the screen. This adjustment is made after the compound microscope has been removed and before the other lens is installed.

Relation of the Optical System to the Thread Helix when Inspecting Screws

When the apparatus is used as a thread projector, the principle employed is different from that of other optical instruments in that the optical system is arranged so that it can be swung to the helix angle of the thread. The entire optical system at all times is lined up along a single central axis, being held in this relationship by the bar *D*, so that the system may be swung about the swivel bushing *E* which contains a vernier scale. The rear part of the system including the lamp, special lens *B* and supplementary condenser *C*, are supported on an arc-shaped rail along which this part of the system may be slid when adjusting the axis of the light beam at the helix angle of the screw.

This method does not give an image which is geometrically similar to the thread contour in the plane of the screw axis, but one which is geometrically similar to that lying in a plane inclined at the mean angle of helix. The two contours are slightly different, but the error from the true outline of the screw thread is so slight that it is rarely considered of importance. For example, for a 60-degree thread and a helix angle of 5 degrees, the angular correction would be 12 minutes; when the helix angle is 2½ degrees the angular correction would be 2 minutes, 40 seconds. It will be seen that the correction factor may be disregarded for even the most exacting commercial work when the helix angle is 2½ degrees or less; even when the helix angle is 5 degrees, the results will be sufficiently accurate for most commercial work.

This method of projecting the screw thread differs from that incorporated in instruments of other makes which are so constructed that the axis of that part of the optical system which serves for illumination is tangent to the thread helix, while the axis of that part which serves to form the image is perpendicular to the axis of the screw. The purpose of the latter arrangement is to project the section of the screw in the plane of its axis. As a consequence, the image is formed by oblique "pencils" of light passing through the margin or edge of the objective lens. The Bausch & Lomb Optical Co. considers that the result obtained in this way is likely to produce an image not always geometrically similar to the screw thread section, owing to the aberration. The centered optical system incorporated in the instrument here illustrated was adopted for the purpose of eliminating these difficulties. The angular error is a well-defined function of the flank angle and of the mean helix angle and can be calculated for all threads.

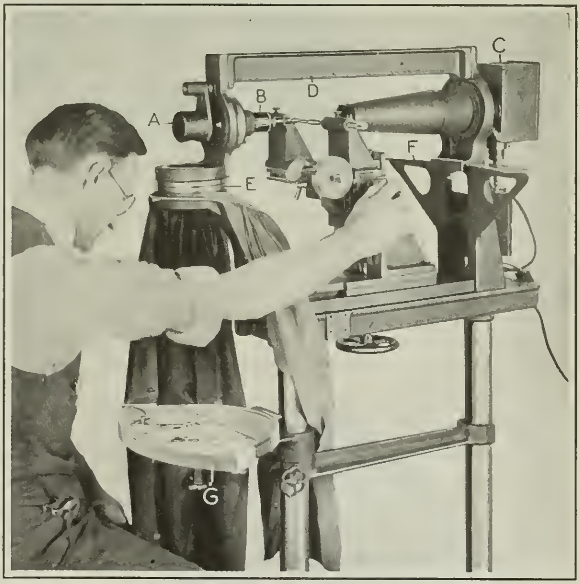

Fig. 2. Measuring the Lead of a Thread Gage

Thread Chart and Photographic Plate Attachments

The adjustable thread chart, Fig. 4, is used for the inspection of threads and is provided with a graduated arc and vernier scale by means of which it can be swung at an angle to bring it into line with the optical system as determined by the reading shown by the graduated scale on swivel bushing *E*, Figs. 1 and 2. A single chart serves for threads of different sizes and various magnifications, because adjustable templets are provided which may be accurately set to any size. These templets have adjustable straightedges which may be set to give the proper width of flat on root or top, corresponding to the pitch of the thread.

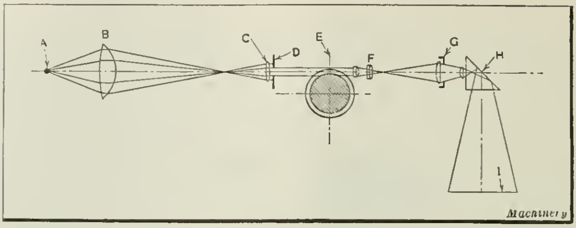

Fig. 3. Diagram of the Optical System

Attachments that Increase the Field of Application

A lead-measuring attachment, which checks the lead to 0.0001 inch, is used when inspecting screw threads. It consists of a dial gage and a micrometer head attached to the side of the cross-slide. This and all other attachments used with the projector are interchangeable on the cross-slide which is machined with a T-slot on the side for convenience in attaching.

A device which facilitates the inspection of screws and which will accommodate work up to 2 inches in diameter, is shown in Fig. 5. This is a universal screw-holder which is attached to the cross-slide in place of the two centers regularly used for centered work. This is very simple in construction and rapid in operation, and its use enables the pitch diameter, root clearance, thread shape, external diameter and accuracy of lead to be quickly inspected. The device supports the screw entirely from the effective diameter of the threads. As many threads as are intended to be subsequently engaged in a tapped hole, are engaged by the blades *A* and *B*. By combining unavoidable errors in lead and diameter, the image on the chart will instantly show whether or not the screw will assemble into the tapped hole.

Other attachments are a sulphur cast attachment by means of which casts may be taken of internal threads; a V-block attachment (see Fig. 1) for holding irregular-shaped pieces, especially lead-screws and similar long threaded work; and a gear attachment. The V-block attachment is simply two blocks each having a vee on the side as well as on top, and a clamping arrangement. The gear attachment, Fig. 6, is also of simple design; it consists of two brackets, each carrying a stud so that gears may be mounted and inspected while in mesh. An indexing pivot can be centered in the tooth spaces, so that as the gears are turned errors in tooth spacing can be detected.

The instrument should be placed in such a way that light will not fall directly on the work chart. A moderately lighted room is satisfactory, so that there need be no inconvenience from working in the dark. To adjust the optical system, the light is turned on, the diaphragm *D*, Fig. 3, opened wide, and the special lens *B* focussed by a lever projecting through the cone in which it is contained. Proper focussing will produce a circle of light about 3/4 inch in diameter on a piece of paper held in the plane of the object. Two screws at the bottom of the lamp housing are then used to centralize this image with respect to the objective lens of the microscope. When this has been done, the set-up remains in this position until it is again required to adjust the system, which should be necessary only when other lenses and eye-pieces are used to obtain greater magnification.

A master gage is then placed between centers (or located in the V-block attachment) and the optical system swung to the helix angle of the thread on the arc-shaped rail *F* in Fig. 1. The setting is read on the graduated swivel bushing *E* and this reading should correspond with that obtained when locating the chart *G* to align it with the axial line of the optical system. To raise or lower the gage, a handwheel underneath the machine is adjusted, while to move the gage horizontally the cross-slide is moved in the manner shown in Fig. 2, by a knob on the right-hand side of the machine.

These adjustments should bring the upper part of the thread into the beam of light where it can be focussed by bringing it back or forth by turning a handwheel at the front of the instrument. A fuzzy outline of the image accompanied by bright line reflections near and parallel to the contour of the thread outline is an indication of poor adjustment, incorrect angular setting of the optical system, or an error in centering the beam of light.

Setting the Universal Chart

Attention is next called to the universal chart, Fig. 4. This should now be rotated so that master lines representing the flanks of the thread coincide with the outline of the image. This determines whether the thread is "leaning" to one side or the other. "Leaning" is one of the most frequent causes of ill-fitting threads and it can be detected at a glance when the image is compared with the flanks of a master thread form. The reading on the graduated arc of the chart should then be compared with that of the

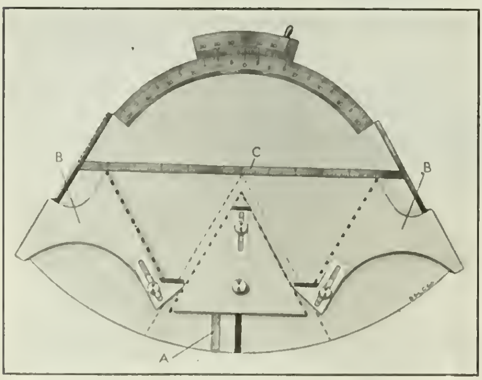

Fig. 4. Adjustable Thread Chart which is Part of the Optical Instrument

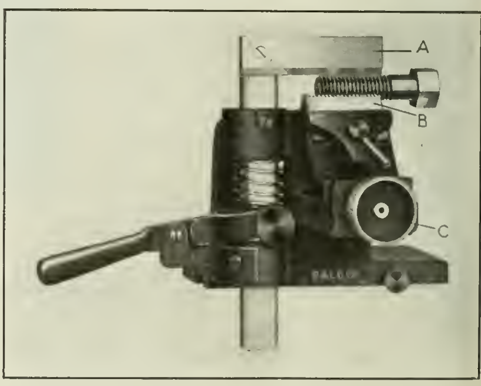

Fig. 5. Universal Screw-holder for Use in Inspecting Machine Screws

vernier on swivel bushing *E*, Figs. 1 and 2, and if they fail to agree it shows that the thread leans—that it is unsymmetrical.

Next determine whether the axis of the gage is parallel to the line of travel of the slide; if it is not, an accurate measurement of lead is impossible. To determine this, adjust the position of the gage so that the image of one end thread will fall on the center templet of the chart. The slide is then adjusted until the edge of the image appears equally distant from both sides of the master lines with a faint thread of light between them. The cross-slide should then be moved in the opposite direction until the thread at the opposite end of the gage casts an image on the chart, bearing the same relation to the master lines as that of the first thread image. If the image from the last thread appears above or below the master outline, it indicates a tapered gage or one that is not true on centers.

It is always advisable as a precautionary measure to rotate the gage by hand after it has been sharply focussed. This may show faults and irregularities in the thread which might otherwise not be detected. Often a gage may be so distorted in hardening that when it is inspected and revolved before the light there will be an irregular movement of the thread image as it travels across the chart. A true helix would show a uniform advance. If the image rises and falls as the gage is being turned, it shows that it is out of round. The most minute irregularities of the thread are thus made obvious.

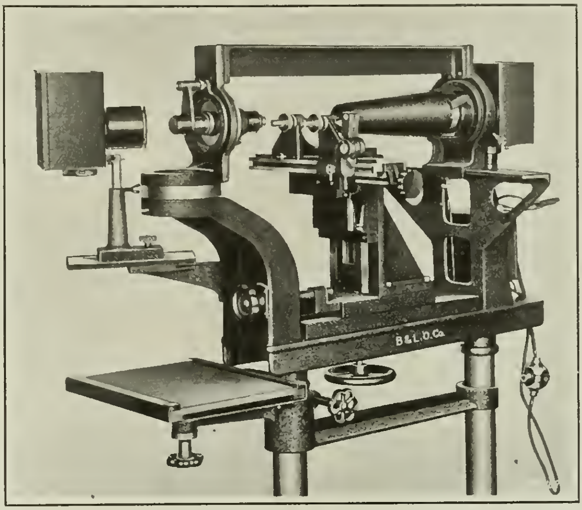

Fig. 6. Instrument equipped with Gear Attachment, Special Optical Arrangement and Photographic Plate Holder

In measuring the lead of a thread, the image of one side of the thread is first made to coincide with one of the master lines on the chart. The dial gage shown in Figs. 1 and 2 is then slid along in the T-slot on the side of the cross-slide until it contacts with the micrometer spindle which is set at zero. The micrometer head does not move; it is attached to the upright support of the cross-slide. The position of the dial gage needle when the spindle is in contact with the micrometer spindle should then be noted and should preferably be at zero to facilitate reading the micrometer.

The cross-slide is then moved back until the image of the next thread (or any other selected thread) is brought up to the same position that the first thread occupied. The micrometer drum is then turned until the spindle advances into contact with the gage spindle and causes the gage to register as before. The micrometer reading is obtained in the regular way. The dial gage merely serves as a reliable zero point and eliminates the sense of touch which often results in errors in micrometer readings.

Use of Optical Instrument to Obtain Actual Measurements

It has been previously stated that actual measurements of screw threads and other parts may be made with the aid of the projector apparatus. To do this the proper objective lens and eye-piece should be selected from the chart prepared by the manufacturers of the instrument, which will give approximately the desired magnification. If a gage 5 inches in diameter having 40 threads per inch is to be measured and the magnification is to be 100 times, a 24-millimeter focal-length lens and a 5-times eye-piece would be used, and the master thread chart would be located about 29½ inches down from the right-angle prism.

To find the exact position of the chart, the centers (similar to the lathe centers) are separated 1/10 inch and they are focussed on a piece of paper on which two reference lines are drawn 10 inches apart. This piece of paper is placed on the chart which is vertically adjusted until the image of the center-points exactly coincides with the reference lines and is sharply focussed. When this condition is obtained the magnification is 100 times.

In obtaining the actual measurements after these adjustments have been made, the thread chart, Fig. 4, is set to one hundred times the actual size of the thread to be compared. To set the chart, the center templet is set to zero on the vertical scale *A*, and the side templets *B* are located so that their edges intersect the scale *C* and indicate one hundred times the actual pitch measurement, which for a forty-threads-per-inch screw, would be 2.50 inches either side of the zero graduation. The auxiliary templets which define the top and the root of the thread are then set by means of a scale on their edges. In the case of a forty-threads-per-inch screw, the width of the flats is ⅛ the pitch multiplied by 100, or 0.314 inch. The chart is then set to the helix angle which in this case is five minutes. To obtain the actual measurement of screw thread elements after the apparatus has been set up to give a definite magnification, divide the width of any space between the image and the master outline by the magnification, which in this case is one hundred, and subtract the quotients from the corresponding standard dimensions.

Inspecting Screws in Quantity

The universal screw-holder, Fig. 5, is used for inspecting automatic screw machine products. The holder is attached to the cross-slide and two pitch blades *B* selected having the required number of threads per inch. One blade is locked firmly in place in an angular position while the other is clamped lightly so that when setting up it may be pushed back and forth without releasing the clamp.

A master thread gage, of the same nominal size as the screw to be inspected, is then laid on the two blades so that it is supported by them. Handwheel *C* is then turned so that the two blades will point radially to the center line of the thread gage. The upper blade *A* clamps the screw in position and is moved up and down by means of a lever and held in place by spring tension. The pressure exerted by this spring is sufficient to cause the unclamped blade to center in the threads of the gage, in which position the blade is clamped. After the holder has been set up, the inspection of screws can be done rapidly. The blades act as a ring gage, only that part of the screw actually used being entered. Adjustments are then made until the top threads of the gage are properly focussed on the comparison chart. Assuming that the chart and optical system has been set up as previously described, the image from this master gage will represent the maximum permissible size of the screw to be inspected. By setting the chart templets to the minimum allowable diameter of the screw, a tolerance zone is established. This working tolerance zone can be quickly established with the adjustable chart arrangement to suit any thread tolerance.

Inspecting Gears with the Projector

With the optical projector it is possible to check the contour of gear teeth, form cutters, etc., and determine at a glance the form, rolling action, center distance, etc., that otherwise would be difficult to ascertain. For handling gears, special brackets (see Fig. 6) are attached to the cross-slide, these brackets having ½-inch diameter studs, over which the gears are placed, using bushings if necessary. The brackets may be positioned so that the gears will mesh; then by rotating them at an even rate the rolling and sliding actions of the teeth may be observed as well as any imperfections in tooth shape. Thickness and height of teeth can be measured to within close limits by employing an adaptation of the method previously described for obtaining actual measurements of screw threads.

The light is passed along the tooth surface at the point of contact (in the case of spur gears) but in this application of the instrument, it is usually advisable to project the image on an auxiliary screen located at right angles to the axis of the optical system and approximately ten feet away. It is important when inspecting the gears with the projector, to see that the face of the gear toward the objective lens is free from burrs at the edge of the teeth. Slight burrs may often erroneously indicate a poor tooth form. It is good practice to locate the face of the gear from which the forming cutter entered in milling the teeth, toward the objective lens. In obtaining the proper center distance, measurements are taken over the studs on which the gears are mounted, using calipers.

The projector is not limited to inspecting spur gears. In the case of spirals, it is necessary to illuminate the face of the gear adjacent to the objective lens by oblique or normal illumination. This is called "opaque" projection. The best results can be obtained from this method of inspection only by having the surfaces of the gear against which the light is directed highly polished so that they will furnish a good reflecting surface. Lapping the surface on a cast-iron plate using fine emery and oil will usually give the desired finish.

The optical arrangement for helical gear inspection, in which the light is reflected to produce the image, is different from that ordinarily used. A special attachment consisting of a lamp housing, is mounted on a bracket bolted to the rear side of the bracket supporting the swivel bushing. The lamp can then be set so that the rays of light from the lamp are directed against the face of the gears or other parts. A 6-volt, 108-watt Mazda lamp is used, fitted with a condenser. The arrangement can be used only with low-power objective lenses.

FINDING SPIRAL ANGLE OF MILLING CUTTER

By C. A. MACREADY

There are several methods of finding the "spiral" or helix angle of a milling cutter, but the writer believes that the one described in the following will be found the quickest and most convenient. The method described also has the advantage of leaving the work in position to be recut in case this is necessary. The procedure in determining the spiral will be given for the purpose of making the method clear. It should be mentioned that the method is the same regardless of whether the cutter is a new one or an old one that has been annealed and turned down until only the bottoms of the tooth spaces remain.

The cutter is first placed on the arbor and index-centers of a milling machine. An indicator is next clamped between the collars on the milling machine arbor in such a position that the point is in contact with one side of the milling cutter tooth. A piece of sheet metal may be used in place of an indicator if no indicator is available or in cases where a groove or tooth is so shallow that it will not give a suitable bearing surface for the contact point of the indicator. The dial on the table feed-screw must also be in position to record the longitudinal movement of the table, and an index-plate having an indexing circle of, say, twenty holes must be used to record the arc of travel through which the milling cutter tooth is revolved.

Referring to the accompanying diagram, let E represent the milling cutter, F the indicator, B the longitudinal distance through which the milling machine table or milling cutter is moved, and D the arc through which the cutter rotates during the longitudinal movement B.

Let A = number of holes indexed;
B = distance traveled by milling machine table; and
$C = 40 \times$ index circle used, or $40 \times 20 = 800$.

The circle can thus be divided into 800 parts by using the

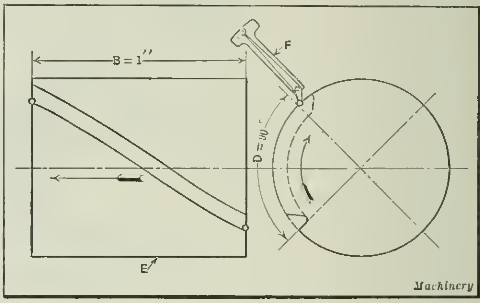

Diagram illustrating Method of finding Spiral Angle of Cutter

20-hole circle. The spiral in inches can now be determined by the formula

$$\frac{C \times B}{A} = \text{length in inches for one complete turn of spiral}$$

Assume that the micrometer dial shows that the table has been given a longitudinal movement B equal to 1 inch, and that the index-plate has been given exactly ten complete turns, the indicator F still registering zero. Then $A = 20 \times 10 = 200$; $B = 1$ inch; and $C = 40 \times 20 = 800$. Substituting these values, we have:

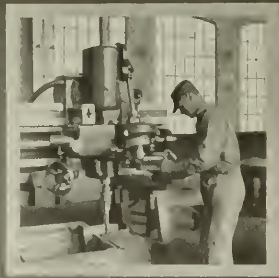
$$\frac{CB}{A} = \frac{800 \times 1}{200} = 4$$

Thus the spiral is found to equal one turn in 4 inches. This is perhaps an ideal illustration of the method, as it will be noted that ten turns of the index-plate or an indexing movement equivalent to 200 holes in the 20-hole circle equals ¼ turn of the work or an arc of rotation D equal to 90 degrees. Now taking a case such as is frequently met with in practice, let it be assumed that A equals 206 (10 turns and 6 holes) instead of 200 as in the previous example. We then have:

$$\frac{CB}{A} = \frac{800 \times 1}{206} = 3.883$$

In this case the lead of the spiral is taken as one turn in 3.89 inches, as this is the nearest spiral given in the table of spirals accompanying the milling machine. The variation from the value 3.89 inches is due in this case to the fact that the index circle used could not register an even number of holes for the arc through which the cutter was rotated.

Letters on Practical Subjects



FEEDING WORK INTO ROTATING CHUCK

The feeder head shown in Fig. 2 was designed by the writer for the purpose of feeding drop-forgings into the rapidly rotating chuck of an automatic turret lathe. The forging for which the feeder head was originally designed is shown in Fig. 1, but the device can be adapted for feeding short-length work of various kinds into a lathe chuck without stopping the machine. For instance, parts made from bar stock of round, square, or hexagon section could be handled readily by a device of this type.

Referring to Fig. 1 it will be noticed that a square boss *A* projects from one side of the drop-forging. In machining this forging, it is necessary to insert the boss *A* in a square hole in the chuck. The machining operations required were as follows: Face one side; turn and thread the edge; and back-face a portion of the side from which the square boss projects. After several methods of chucking the work had been proposed and rejected as impracticable, the writer suggested that the work be put in the chuck without stopping the machine. It was first thought that this was impracticable, as it was believed that the square boss on the forging would have its corners knocked off in the effort to make it enter the revolving chuck jaws. If the work had been held stationary, this undoubtedly would have been the case, but the feeding head permits the work to revolve at the same speed as that of the chuck with just sufficient frictional drag at the entering position to cause the work to slip until the square corners of the boss match the hole in the spring jaws of the automatic chuck.

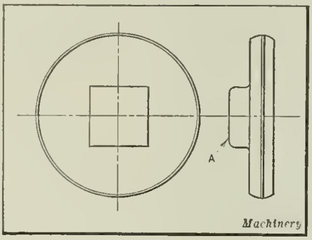


Fig. 1. Type of Forging handled by Device shown in Fig. 2

If the forgings are pressed against the chuck too hard at first, there will be no slipping and the forging will not enter the chuck unless it happens to be in the correct position at the instant of contact. To obtain a light pressure at first when the work is being made to enter the chuck a light spring *D* of long stroke (Fig. 2) is used. A stronger spring *E* comes into operation near the end of the turret head stroke which holds the forging firmly against the chuck during the closing action of the jaws. A small spring *F* at the end of the spindle provides pressure between the spindle and the sleeve *B* at the cup end that holds the forging. This causes a frictional drag that is sufficient to make the feeder head revolve at a little slower speed than the chuck until the work has been properly entered.

As the revolving element is acted upon by two springs, it is provided with a sleeve *B* which holds the springs and which is free to slide back and forth in bushing *C*. Bushing *C* is held in turret bracket *H*, and a key *J* in the bushing prevents sleeve *B* from revolving. The small finger springs *G* hold the forging in the feeder head cup of spindle *A*. These finger springs open and release the forging on the backward stroke of the turret. If the friction drag spring *F* is screwed up too tight, spindle *A* will not turn and the forging will then slip inside the finger springs *G*. While this will permit the work to be loaded into the chuck it subjects the finger springs to undue

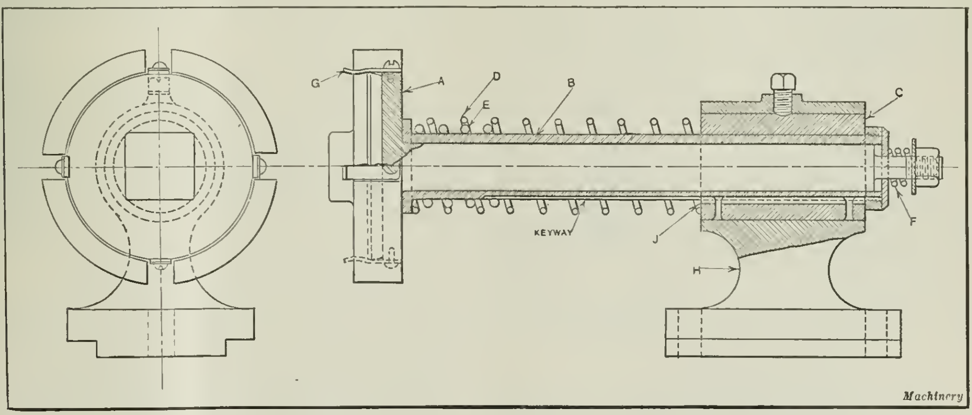

Fig. 2. Device designed for feeding Drop-forgings into a Rotating Chuck

wear due to the rough scale on the forgings. Several machines were equipped with feeder heads that were not provided with revolving spindles but depended on the slipping of the finger springs to obtain the desired results. This arrangement, however, was not so satisfactory as the design illustrated.

Lyells, Va. W. R. WARD

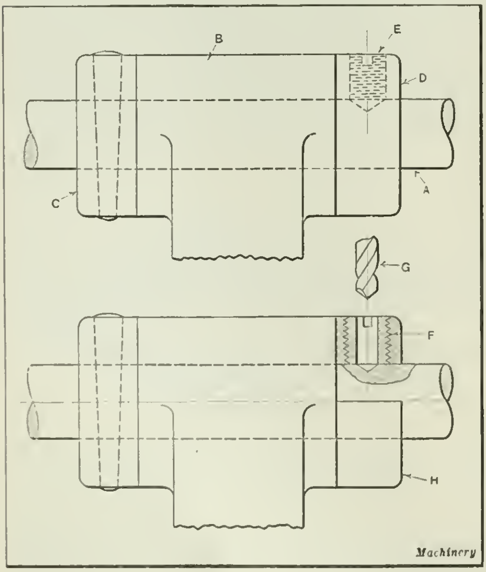
SPOTTING A SHAFT FOR A COLLAR SET-SCREW

In the upper view of the accompanying illustration is shown a shaft *A* which runs in a bearing *B*. The shaft is held in position by two thrust collars *C* and *D*. The thrust collar *C* is pinned to the shaft, while collar *D* is held in place by a conical pointed set-screw *E*. Shaft *A* is spotted to receive the point of the set-screw after the shaft is assembled in the bearing. The writer has frequently encountered this construction, and in most cases has found it difficult to locate collar *D* properly on the shaft by the methods generally employed.

It is quite common practice to spot the shaft with the tap drill used to drill the set-screw hole in the collar, the procedure being first to drill the collar with the tap drill and then use the collar as a drill jig for spotting the shaft. After being tapped, the hole will not always line up properly with the spot on the shaft. Thus considerable end play between the collar and the bearing often results, which must be taken up in some manner. In order to overcome this difficulty, a number of spotting bushings like the one shown at *F* were made up from headless screws. These bushings were made of different sized screws from 3/16 inch up.

The holes in the bushings *F* were made as large as they could be without weakening the bushings so much that they would be likely to break during the hardening operation. These jigs or bushings were all provided with slots to receive the blade of a screwdriver. By placing the spotting bushing *F* in the tapped hole of a collar *H*, which is to be used on the shaft, and then bringing the drill *G* down through the hole in the center of *F*, the shaft can be spotted very quickly and as accurately as it could be done with a more expensive tool or jig.

Bridgeport, Conn. A. H. PONELEIT and A. BIRCHALL

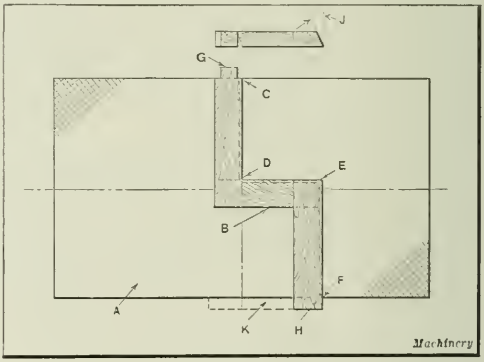


Method of spotting a Shaft for locating a Collar Set-screw

STOPPING-OFF PIECE FOR FLOOR-PLATE PATTERNS

Patterns for diamond-checked floor-plate castings of standard size are kept in stock by some companies. When plates of special shape or design are required, it is common practice to use a pattern of standard size in making the mold, and employ a stopping-off piece to cut the mold down to the desired size and shape. If a floor-plate is required of a size larger than any provided by standard patterns, blocks are added to one of the regular patterns to obtain the desired size. In no case should a regular pattern be cut if it can be avoided. When patterns provided with stopping-off pieces are to be sent away to a foundry where the molding operations cannot be observed, it is necessary to provide some means of insuring the proper location of the stopping-off pieces. Chalk marks on the pattern showing the location of the stopping-off piece are not to be relied upon, as they wear off quickly.

The best plan is to make the stopping-off piece with ends that project beyond the edges of the floor-plate pattern, as shown in the accompanying illustration, and attach temporary blocks or prints to the edges of the pattern. The pieces attached to the pattern should correspond to the projecting ends of the stopping-off piece, so that they will leave pockets in the mold into which the ends of the stopping-off piece will fit. In order to prevent the stopping-off piece from being reversed in the mold, one of its ends should be made smaller than the other. The corresponding print or



Stopping-off Piece for Floor-plate Pattern

block attached to the pattern should, of course, also be made smaller. By this arrangement it would be impossible for the molder to reverse the position of the stopping-off piece, which he might easily do if the ends were made flush with the sides of the pattern.

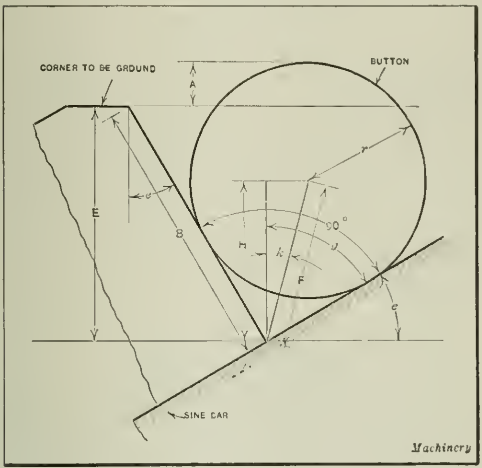
In the illustration, *A* represents a floor-plate pattern of standard size, and *B* a stopping-off piece designed to stop off the casting along line *CDEF* so that the floor-plate will have the shape indicated at the left of the stopping-off line. After making a mold of the complete floor-plate in the usual manner, the stopping-off board is put in place on the mold, with the projecting ends *G* and *H* in the pockets formed by the corresponding pieces attached to the plate pattern. The space to the right of the stopping-off piece is then filled in with molding sand to the top of the board, after which the latter is removed, thus completing the mold.

In order to obtain a close fit between the edges of the cast-iron floor-plates, a slight bevel is given to the stopping-off board along the stopping-off line. The angle at *J*, although somewhat greater than that used in actual practice, serves to indicate the method of beveling the stopping-off piece. In order to prevent the stopping-off piece from pressing down too hard on the check impressions in the mold, a large block, such as indicated by the dotted lines at *K*, is sometimes attached to the pattern in place of the smaller blocks. Corresponding blocks attached to the stopping-off piece then serve to support the weight of the stopping-off board, so that the check impressions will not be disturbed.

Kenosha, Wis. M. E. DUGGAN

CHECKING A TOOL-ROOM JOB

This article describes a method of determining when an angular corner of a block is so formed that one side of the block will have a given width B, as indicated in the illustration. The procedure is to mount the work on a sine bar as shown, with the sine bar set at the angle to which the corner of the block has been ground. The button is set on the sine-bar and in contact with the work.



Method of checking a Tool-room Job

The known dimensions are as follows:

c = angle to which corner of block is ground;

B = width of side of block; and

r = radius of button.

With these dimensions it is required to find the difference in height between the corner of the block and the top of the button, as indicated by dimension A.

By trigonometry we have

$$E = B \cos c \quad \text{and} \quad F = r \operatorname{cosec} 45 \text{ degrees}$$

Then

$$g = 90 \text{ degrees} - c \quad \text{and} \quad k = g - 45 \text{ degrees}$$

By trigonometry

$$H = F \cos k$$

and

$$H = r \operatorname{cosec} 45 \text{ degrees} \cos k = 1.4142\, r \cos k$$

Then

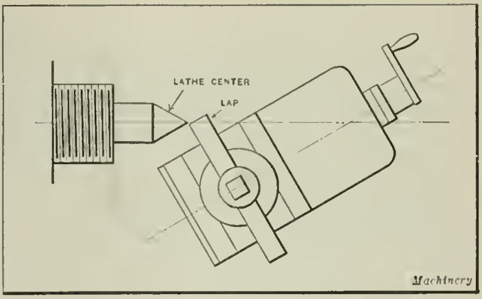
$$A = H + r - E \text{ or } E - (H + r)$$

The value taken depends upon whether the top of the disk is above or below the top of the machined corner. In the case illustrated the top of the disk is above the top of the machined corner so that $A = H + r - E$.

Flint, Mich. W. G. HOLMES

TRUING UP A LATHE CENTER

In order to face both ends of a piece of work held between centers on a lathe, it is usually necessary to reverse the piece, or turn it end for end. It is often found, however, that the work will not run true after its position has been reversed. This is usually because the headstock center does not run true. The amount that the center runs out may be so small that it cannot be detected unless a very sensitive indicator is used, and yet it may be sufficient to cause considerable inaccuracy in the work. It is very difficult to keep the centers absolutely true, and it has been the writer's experience that even after a center has been ground with a toolpost grinder, it will still run out from 0.00025 to 0.0005 inch.



Method of truing up Lathe Center with Cast-iron Lap

It is hard to tell just what causes this inaccuracy, as in the cases noted there was apparently no play or shake in either the lathe spindle or the grinder spindle. As a test, a center thus ground was indicated, and the spindle marked at the point corresponding with the high spot on the center; then another center was ground, using exactly the same set-up. In the case of the second center the position of the high spot was between 90 and 100 degrees from the point marked on the spindle in the first instance. This test would seem to show that the inaccuracy was not due to the spindle hole running eccentric with its outside diameter. It would be interesting to receive some comments as to the reason for the inaccuracy recorded by these tests.

The writer has found, however, that the inaccuracy referred to may be corrected in the following manner: After removing the grinder a cast-iron lap is clamped in its place, as shown in the illustration. No cutting compound is used, the structure of the cast iron being such that the desired result is obtained without the application of any abrasive. A few drops of oil applied to the lap and a little pressure of the lap on the center is all that is required. The compound slide, of course, is left in the same position that it occupies when grinding.

Cleveland, Ohio WILLIAM WILSON

OBSERVATION TIME-STUDY TICKET

The $8\frac{1}{2}$- by 11-inch observation sheet ordinarily employed in recording time-study data for use in setting piece-rates is well adapted for cases involving a comparatively large number of operation details. However, when there are but few details that require studying, a small size observation ticket such as shown in Figs. 1 and 2 will be found more convenient and economical.

Ordinarily, if the time-study man makes a trip to the shop without his large pad of observation sheets (as often happens) and is called upon to make an observation, he must return to his office for the pad. But if he is provided with a small size pad like the one described in this article, he will invariably carry it in his pocket ready for use. In ruling up the small sheets, the writer had this point in mind, and accordingly made the size about 6 by 4 inches so that a pad made up of the sheets could be easily carried in the pocket.

To those not familiar with the piece-work system, the following description of the procedure in making a time-study and recording the necessary data may be of interest. Let it be assumed that the rate-setter is called into the shop to make a time-study of a certain piece of work. It should be mentioned here that the observation ticket is made up in pads with the side marked "Detail Operation" (as shown in Fig. 1) to the front. The rate-setter first lists the detail

Fig. 2. Reverse Side of Ticket shown in Fig. 1

operations, as shown in the illustration in the left-hand column, and then proceeds to make a time-study on ten pieces of work.

This is done by taking continuous readings with the stop-watch. For instance, on the first piece the stop-watch registered 0.1 minute for the chucking operation, and 0.4 at the end of the second operation, which is that of drilling and rough-turning. After recording the stop-watch readings for ten pieces of work, the time for each detail operation is obtained by subtracting the stop-watch reading for the preceding operation from that of the operation under consideration. The actual time for the detail operation is then placed in the lower half of the space opposite the name of the operation and in the column used for that particular piece.

The average time for each detail operation is then calculated and placed in the column provided for it. The minimum time is also filled in as shown. The piece-rate is set on the work by the formula on the lower half of the ticket. After this has been done, the opposite side of the ticket is filled in as shown in Fig. 2, and the record cards made out and sent to the shop. The observation tickets are then filed away for future reference.

Aurora, Ill. JOHN J. BORKENHAGEN

SPECIAL SCREW MACHINE CHUCK

The screw machine chuck shown in the accompanying illustration was designed to be operated by means of the draw-rod mechanism of the screw machine. The clamping is accomplished without any longitudinal movement of the collet, and the work is located against a stop-member which is independent of the collet. This construction prevents the threads of the work from binding on those of the collet when the latter is released.

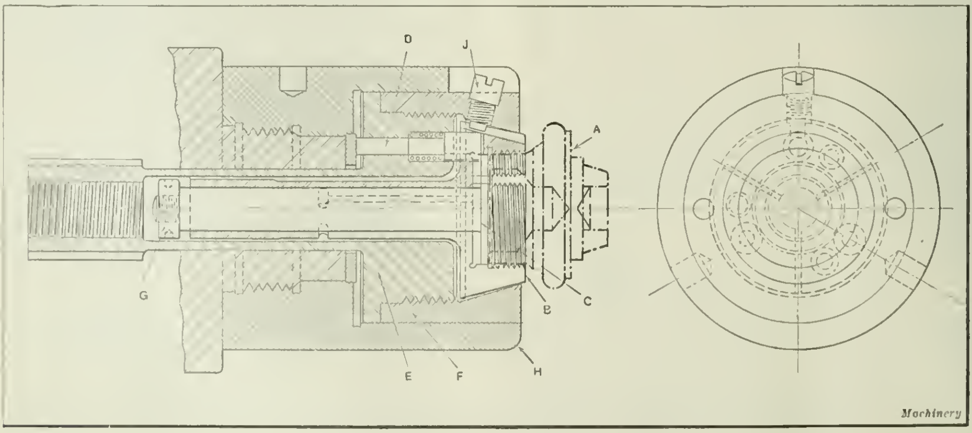
The work *A*, shown by the heavy dot-and-dash lines, is threaded into the collet *B*, and bears against the stop *C*, the thrust being transmitted against the spindle of the machine through the medium of the three spring-actuated plungers *D*. The plungers *D* are located in the collet-closing sleeve parts *E* and *F* which are threaded together. The collar *G* retains the stop *C*. The collet *B*, the closing sleeve *F*, and the chuck cap *H* are keyed together by the screw *J*.

Waynesboro, Pa. D. A. NEVIN

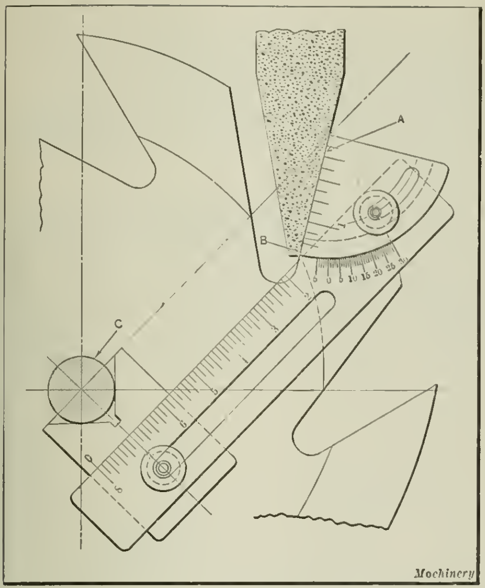
SETTING GRINDING WHEELS FOR SHARPENING HOBS

The wear to which grinding wheels are subject in operation is generally distributed unevenly over the working surface of the wheel. This is very noticeable in wheels used for form and angle grinding. In grinding gashes or flutes of hobs, the wheel is usually worn away fastest at the largest diameter as the wheel is weakest at this edge and has much more metal to remove. In form cutter and hob grinding, it is the general practice to make such allowances in truing the grinding wheel and setting the machine as will compensate for this uneven wear.

In sharpening hobs by grinding the tooth faces with the wheel set as indicated in the illustration, the wear on the wheel is less at point *A* than at the periphery *B*. Therefore if the grinding face is trued and set to grind work on a radial line, the finished surface will have a negative rake.



Special Screw Machine Chuck, operated by the Draw-rod Mechanism



Testing Angle of Wheel set to grind Hooked-tooth Cutter

This results from the more rapid wear near the periphery of the wheel, which actually changes the angle of the grinding face.

In order to produce a tooth having a radial face, it is necessary to set the wheel to grind "hooked" or "under-cut" a certain amount to allow for abrasion. To produce a hooked tooth having an under-cut of 8 degrees, for instance, it is necessary to set the wheel to a somewhat sharper angle, say, 9 or 10½ degrees. If this allowance is correct, the face of the tooth will have approximately the desired angle. No definite data regarding the amount of allowance, however, can be given, as this depends on too many variables. By measuring the tooth face angle after grinding, and then comparing this measurement with the angle of the grinding wheel face at the beginning of the operation, an operator soon learns what allowance to make for wheel abrasion. The allowance naturally depends upon the hob being ground, the kind of wheel used, and the kind of grinding machine employed. In order to reduce the allowance to a minimum, it is necessary to use a wheel of the correct grade and grain, and also to run the wheel at the correct speed, and employ a machine having well lubricated bearings of ample size.

A soft wheel will be worn away very rapidly when mounted on a light weight machine which allows considerable vibration, while a hard fine wheel will be abraded less rapidly. The hard wheel, however, is likely to burn the work, and has a comparatively low production rate. Again, if the wheel is too soft and is run at too low a speed, with a feed that is too small, or if the depth of cut is too heavy, the hob may actually turn the wheel down faster than the wheel can grind the hob. The difficulty in evolving a formula for determining the amount of allowance for wheel abrasion is therefore evident.

In form and angle grinding, it is necessary to have some means of gaging or testing the angle of the grinding surface of the wheel before and after the grinding operation. A gage that has proved exceptionally useful for this purpose is shown in the accompanying illustration. This gage makes it unnecessary to have separate radial setting gages and templets for hobs of different diameters and tooth forms. Another advantage is that the gage can be adjusted to include the allowance required to compensate for wheel abrasion.

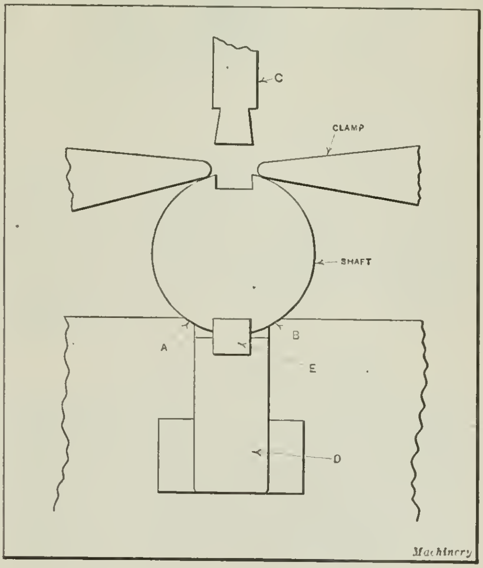
The capacity of the gage is for hobs and form cutters from 2 to 8 inches in diameter, and from 5 degrees negative rake to 30 degrees positive rake. This gage may be used on a hob or formed cutter grinder with the hob in position, as the measurements are taken from the tailstock center shown in cross-section at *C*. In the illustration the gage is shown set to test the angle of a grinding wheel for an 8-inch hob having an extreme hook or rake of 30 degrees, and a cutting face 1⅜ inches deep. This angle is not recommended; it merely illustrates the maximum angle to which the gage may be set. In applying the gage, the table of the machine is adjusted so that the tailstock center which supports the hob is directly under the center of the grinding wheel. The V-end of the gage is placed against the center *C* and the protractor edge swung upward into contact with the wheel as illustrated. Thus the gage may be employed for setting wheels to grind straight, left- or right-hand spiral flutes.

Bridgeport, Conn. HARRY E. HARRIS

CUTTING KEYWAYS IN LONG SHAFTS

The writer was recently confronted with the problem of cutting two ⅜-inch keyways diametrically opposite each other and extending the full length of a shaft 21 feet long. The shaft was 1¾ inches in diameter and the two ⅜-inch keyways were required to be spaced exactly 180 degrees apart. The accurate spacing of the keyways was necessary, as the shaft was required to be a good sliding fit in the broached holes of twenty-five steel gears. These gears, when assembled on the finished shaft, were required to slide the full length of the shaft.

The accompanying illustration shows diagrammatically the method devised by the writer for locating and holding the shaft on the planer bed. The table of the largest planer available was 20 feet long, but by allowing the shaft to overhang a little at each end it was found possible to take a cut of the required length. The first step was to plane a small bevel on the edges *A* and *B* of one of the planer T-slots so as to get a true surface on which to lay the shaft. The shaft was then clamped in place in the trued-up slot. The cutting tool *C* was set central with the shaft by means of a



Cutting Keyways in Opposite Sides of a Long Shaft

dial indicator, clamped to a small parallel which was held first against one side of the shaft and then against the other, the tool being adjusted until the indicator registered the same on each side. The first keyway was then cut to the required depth.

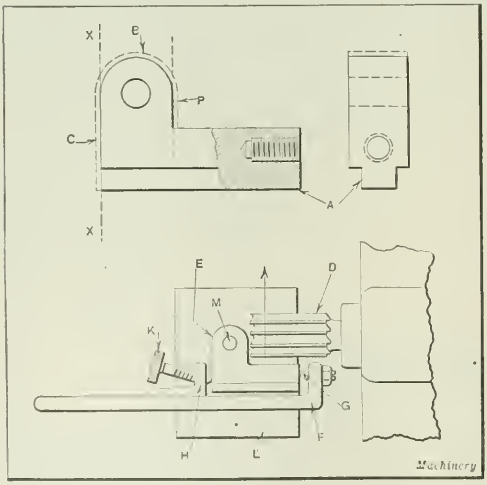
The shaft was next removed, and a cast-iron block *D*, about 4 inches long, was driven down into one end of the planer T-slot. Then, without shifting the cutting tool a slot or keyway was cut in the cast-iron block, after which the key *E* was carefully fitted in the slot and the shaft put back in place on the planer table. The keyway of the shaft, fitting over the key *E*, served to locate the shaft in the proper position for cutting the second keyway. The finished shaft was found to be a good fit in the broached holes of the gears and no trouble was experienced in sliding any of the gears the full length of the shaft.

Cleveland, Ohio CHARLES OWEN LEWIS

MILLING A CURVED SURFACE WITH AN END-MILL

Work that goes through the shop in a hurry is likely to suffer from too much haste, and when the parts are assembled it may be found that they will not fit properly. The writer saw a case of this kind a short time ago. The work that was wanted in a hurry consisted of a small brass casting like the one shown at *A* in the illustration. About 100 of these pieces were made up on very short notice to be shipped as soon as possible. Through an error in making the pattern the castings had an excess amount of stock at *B*, *C* and *P*, so that when an attempt was made to assemble the parts serious interference was encountered. There was no time to make a form cutter, and nothing was available in the tool-crib that was anywhere near the size that was required.

The work was done rapidly in the following manner and rushed to completion. The portion *C* was milled away on



Milling a Curved Surface with an End-mill

line *X-X* by holding the work in a vise mounted on a hand milling machine. While this was being done by another man the writer found a cast-iron plate *L* and drilled a couple of holes in it so that it could be fastened to the milling machine table. A drill rod plug *M* of suitable size was driven into plate *L*. A $\frac{1}{4}$- by 1-inch strap *F* was bent as shown, and a pointed pin *G* inserted at one end. A short piece of stock was bent and fastened at *H* so that the thumb-screw *K* could be applied to this end of the work to clamp it to the handle.

The work *E* was placed on the stud *M* and an end mill *D* used in the spindle of a hand milling machine. The table was fed forward in the direction indicated by the arrow to finish the side of the work at *P*. The lever *F* was then pulled around by hand to generate the curved surface at *B*. By this makeshift method the work was gotten out in time for shipment and within a sufficient degree of accuracy to meet requirements. ALEX DOWEL

ALIGNING STOCK GUIDE OPENING IN STRIPPER PLATE

The proper alignment of the stock guide opening in the stripper plate of a progressive die is often a puzzling problem, and few diemakers have any definite method of accomplishing this. If the stock guide is not properly aligned,

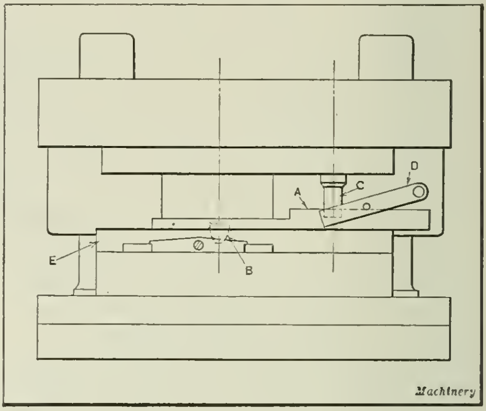


Diagram showing Method of aligning Stock Opening in Stripper Plate

the stock will be pulled over by the pilots. The accompanying illustration shows a simple method of obtaining accurate alignment. With this method a strip *A* having an offset is used. The thin end of this strip is located against the pilot *B*, and the heavy end is placed against the corresponding perforating punch *C*. A pair of small parallel clamps *D* may be used to hold the strip *A* in position.

After clamping the strip in place, the die is closed, as shown in the illustration, and a line scratched on the stripper plate *E*, using the edge of strip *A* as a guide. This line makes it a very simple matter to set up the work properly for machining the opening for the stock. The accurate location of the stock guide slot by this method will save many broken pilots and eliminate much repair work. When this method is employed the die does not need to be finished on any of its sides to facilitate laying out the work as it is commonly done. On work that does not require great accuracy, it is simply necessary to lay a templet on the die and drill the required holes.

The offset strip *A* is also of value in testing the alignment of dies which do not function properly. For this work, a line is first scribed on the stripper plate, as previously described. The stripper plate is then mounted on an angle plate, where it is aligned in a horizontal position, using the scribed line as a guide. The parallelism of the stock opening with respect to the scribed line is tested by running an indicator along the edge of the stock opening. If it is found necessary to remachine the stock opening in a shaper or milling machine, the scribed line is simply transferred to the opposite side of the plate by means of a surface gage while the stripper is mounted on the angle-plate. The vise of the machine can then be swung to whatever angle is required to machine the opening parallel with the scribed line

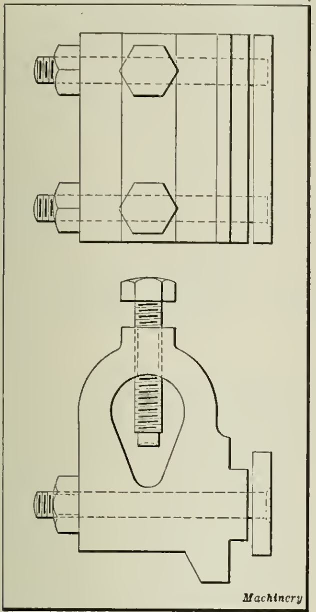
BORING-BAR HOLDER

The accompanying illustration shows a boring-bar holder designed for use on a lathe. It is clamped to the compound rest, and a slot of special shape is cut in it so that boring-bars of various diameters can be accommodated and held in place by the screws. The simplicity of the construction and the range of work for which it may be used will be apparent to those familiar with the use of a device of this kind. The substantial construction and method of attaching this device make it well suited for heavy work.

E. W. Cable
Butte, Mont.

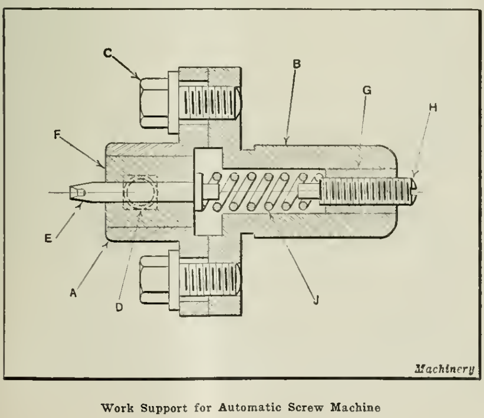


Holder for Boring-bars of Various Diameters

SCREW MACHINE WORK SUPPORT

An adjustable work support for an automatic screw machine is shown in the accompanying illustration. This support has proved useful in tooling up a No. 00 B & S machine for handling small work, the hole in the end of support *E* being 1/16 inch deep and 0.028 inch in diameter. Parts *A*, *B*, *C*, and *D* are standard products of the Brown & Sharpe Mfg. Co. Parts *A* and *B* must, of course, be machined to receive the other parts of the tool-holder.

The tool-steel piece *F* is hardened and ground to a snug fit in part *A*. The tool-steel support *E* is also hardened and ground and is a sliding fit in part *F*. Brass bushing *G* is a driving fit in part *B*. Spring *J* is adjusted by screw *H*. The size of the wire used for the spring depends upon the kind and size of stock being operated on. E. W. L.

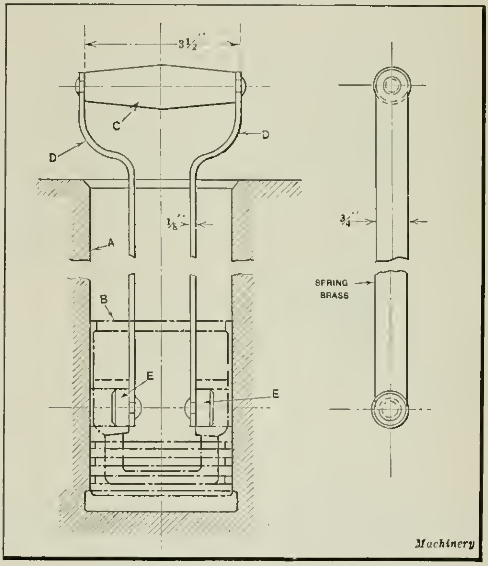


Work Support for Automatic Screw Machine

TONGS FOR FITTING PISTONS IN CYLINDERS

The tongs shown in the accompanying illustration are designed to facilitate sliding a piston up and down in a cylinder block when fitting the piston to the cylinder bore. The cylinder bore is shown in section at *A*, while the piston is represented by dot-and-dash lines at *B*. The tongs are made up of a handle *C* and two straps *D* made of spring brass. To the end of each of the spring straps is riveted a small plug *E*. These plugs are made about 0.005 inch smaller than the wrist-pin hole so they can be easily inserted. In attaching the tongs to the piston, it is only necessary to press the two straps together, insert the ends in the piston, and then allow the straps to spring back so that the plugs *E* will enter the wrist-pin holes.

Pittsburg, Pa. William Owen



Tongs used in fitting a Piston in a Cylinder

HOLDER FOR PENS

Lettering and ruling pens, as well as writing pens, may be kept in first-class condition when not in use, by thrusting them into a jar of BB shot which has been moistened with castor oil. The oil-covered surface of the shot supplies just enough oil to prevent ink from drying on the pens, thus eliminating the principal cause of corrosion or rust. When kept in such a holder, the pens will be shiny and clean each time they are removed and wiped for use.

Auburndale, Mass. Frank H. Jones

Questions and Answers on Practical Subjects

TANGENCY PROBLEM

P. L. W.—Referring to the accompanying diagram, please show how to calculate the radius r of a circle which passes through point C of square $ABCD$ and is tangent to the sides AD and AB? The dimension a of the square is known.

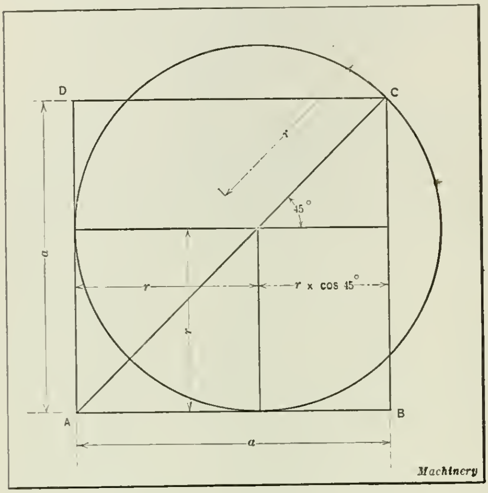


Diagram used in solving Tangency Problem

A.—Referring to the diagram,

$$a = r + r \times \cos 45 \text{ degrees}$$
$$= r\,(1 + \cos 45 \text{ degrees})$$

Hence

$$r = \frac{a}{1 + \cos 45 \text{ degrees}}$$

SIZE OF TAP DRILLS

H. S. A.—What is the correct relation between the diameter of a tap and the drill which precedes it, and to what extent is the size affected by different materials?

A.—There is some variation in the practice of different manufacturers even when tapping the same general class of work, but as a general rule, in manufacturing practice, the drilled holes are large enough to allow for a tapped thread having a depth equal to about three-fourths of the standard depth. On certain classes of work, one-half of the standard thread depth is considered sufficient. So far as strength is concerned, threads tapped to one-half the standard depth are satisfactory; in fact, a bolt subjected to an axial load will break instead of stripping the threads; this applies to a U. S. standard thread inserted in an ordinary cold-punched nut.

When tapping soft material such as copper, drawn aluminum or Norway iron, the holes should be somewhat larger than in the case of harder crystalline materials such as cast metal. If the holes in the soft tough materials are too small, the tops of the threads are likely to be torn off, so that the effective depth of the thread is really less than it would be if the hole were originally larger. Generally speaking, it is safer to drill tap holes too large rather than too small, because three-fourths of a full bearing will give all the strength required.

DESIGNER'S PROBLEM

C. K.—Please show how to find angle x in the accompanying diagram. This angle is required in working out the design of steel wheels.

A.—To find angle x as indicated in the diagram, first draw lines AB, AD, and EB. We now have two right-angle triangles, ACD and ECB.

Now

$$AB = \sqrt{AF^2 + FB^2}$$
$$\text{Sin } a = \frac{AD}{AC} = \frac{EB}{CB}$$
$$AC + CB = AB$$

Therefore,

$$\text{Sin } a = \frac{AD + EB}{AB}$$
$$\text{Sin } b = \frac{AF}{AB}$$
$$\text{Angle } e = 180 \text{ degrees} - (a + b)$$
$$x = 90 \text{ degrees} - e$$

Substituting the numerical values given in the diagram, we have

$$AB = \sqrt{3.75^2 + 3.1875^2} = 4.92165$$
$$\text{Sin } a = \frac{3 + 1.625}{4.92165} = 0.93972$$
$$a = 70 \text{ degrees } 18 \text{ seconds}$$
$$\text{Sin } b = \frac{3.75}{4.92165} = 0.76194$$

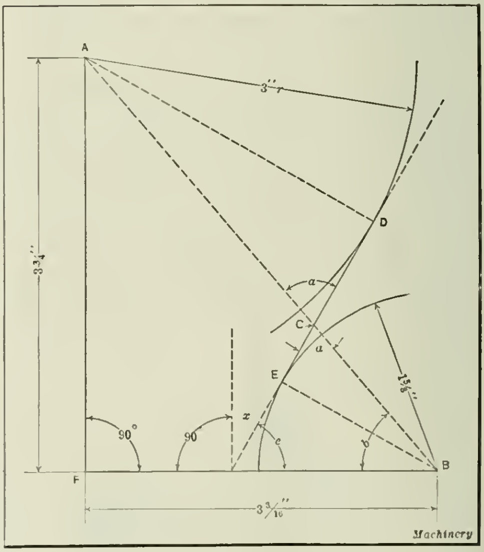

Diagram for solving a Designer's Problem

$$b = 49 \text{ degrees } 38 \text{ minutes } 9 \text{ seconds}$$

Therefore

$$e = 180 \text{ degrees} - (70 \text{ deg. } 18 \text{ sec.} + 49 \text{ deg. } 38 \text{ min. } 9 \text{ sec.})$$
$$= 60 \text{ degrees } 21 \text{ minutes } 33 \text{ seconds}$$

and

$$x = 90 \text{ degrees} - (60 \text{ deg. } 21 \text{ min. } 33 \text{ seconds})$$
$$= 29 \text{ degrees } 38 \text{ minutes } 27 \text{ seconds}$$

ALLOWANCES FOR SHRINKAGE FITS

By A. DESIGNER

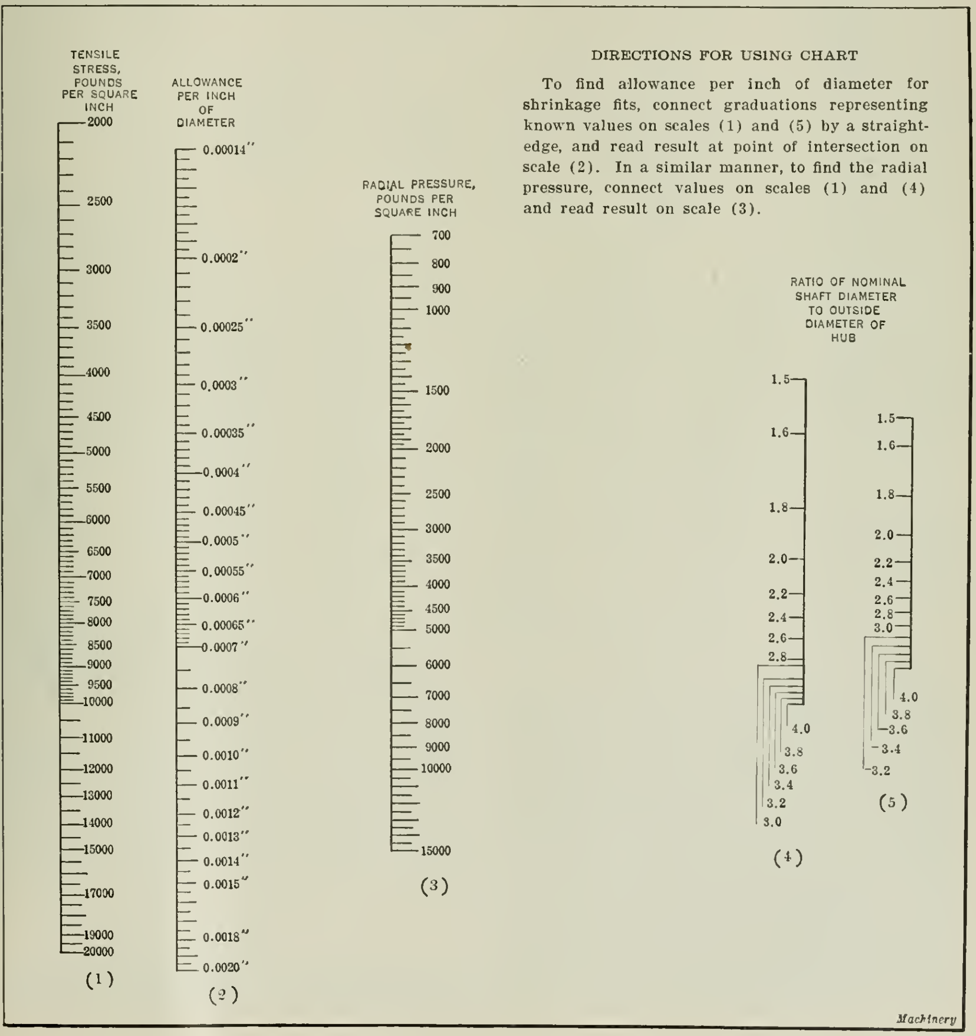
In calculating shrinkage fits, there are two main factors to be considered. The first and most important is the stress in the hub at the bore, which depends chiefly upon the shrinkage allowance. If the allowance is too large, the elastic limit will be exceeded and permanent set will occur; or, in extreme cases, the ultimate strength of the metal will be exceeded and the hub will burst. The second factor may be referred to as the intensity of the grip of the fit, which depends chiefly upon the thickness of the hub; the greater this thickness, the stronger the grip, and vice versa.

The formulas given in MACHINERY'S HANDBOOK on page 886 for determining the allowance per inch of diameter to be made for shrinkage fits, have been used in developing the accompanying chart. This chart is for use when the hub is of cast iron and the shaft of steel. A similar chart (not shown) has also been worked out by the author for use when both the hub and the shaft are of steel. Besides giving the allowance per inch to be made, the chart also gives the radial pressure resulting from the intensity of the grip of the fit, the formula being obtained from MACHINERY'S Reference Book No. 89.

To illustrate the use of the chart, let us assume that we have a cast-iron hub and a steel shaft, the internal and external diameters of the hub being in the ratio of 1 to 1.5. The tensile stress in the hub, which is of cast iron, may be taken as 4000 pounds per square inch. The problem is to determine the amount of allowance per inch for a shrinkage fit. First lay a straightedge across the chart, connecting 4000 on the tensile stress scale with the ratio 1.5 on the scale marked (5). Then on scale (2) read the allowance per inch, which in this case is between 0.00029 and 0.0003 inch. In practice, the latter value would no doubt be used.

The magnitude of the radial pressure exerted by the fit is next desired. The formula for this is $P = TC$, where P = radial pressure; T = tensile stress of the material used; and C = a constant which is dependent upon the ratio of the external and internal diameters. Then, by connecting the

CHART FOR DETERMINING ALLOWANCE PER INCH OF DIAMETER FOR SHRINKAGE FITS AND THE RESULTING RADIAL PRESSURE WHEN THE HUB IS CAST IRON AND THE SHAFT STEEL



tensile stress, 4000 pounds in this case, with the same ratio, 1.5 on scale marked (4), we read, on scale (3), 1400 pounds as the radial pressure exerted by the fit.

A little study of the chart will disclose some interesting facts that are not so apparent when use is made of tabulated values. For example, if we increase the tensile stress in the hub to 6000 pounds per square inch, maintaining the same diameter ratio, the resulting allowance per inch of diameter is increased to 0.00044 inch and the radial pressure correspondingly increased to approximately 2100 pounds. On the other hand, if we, arbitrarily, adopt an allowance of say 0.001 inch per inch of diameter, it is found that with the same ratio the tensile stress is jumped up to 13,500 pounds per square inch and the radial pressure is increased to 4700 pounds per square inch.

It can readily be seen that the determination of the allowance for this class of fits should be given careful thought in order to prevent the ultimate strength of the material and its elastic limit from being exceeded. To approach the danger point too closely invites trouble. It will be evident that the chart can be worked inversely, that is, if the allowance is known, the radial pressure or tensile stress can be determined. It is necessary, however, that two of the factors be known, or assumed, in order to find the third.

* * *

In equipping a plant and in buying new machinery, great care is usually taken to see that the best machine for the purpose is obtained. The buying of small tools and tooling equipment is not always done with the same care; yet small tools very largely determine manufacturing costs. In plants where quantity as well as quality of the product is the main consideration, the same care should be given to obtain the most effective tooling equipment as is given to the selection of machine tools. As a rule, it requires more definite knowledge of machining methods and of tools available in the market to properly select a tooling equipment than it does to select a machine tool. In some shops, all tools are passed upon by a special department, whether the tools are bought from the outside or designed and made in the tool-room of the shop. Such a tool ordering and inspection department insures uniformity and makes it possible to have someone who is constantly looking out for the quality and type of tooling equipment used. This system can also be extended to the care for the entire tooling equipment.

COUNTERBORES OR SPOT-FACING TOOLS WITH INTERCHANGEABLE CUTTERS

By EDWARD H. TINGLEY
Research Engineer, Delco Light Co., Dayton, Ohio

The counterbores or spot-facing tools described and illustrated in this article were developed for use in the plant of the Delco Light Co., Dayton, Ohio, where they have been employed for a long time with marked success. In working out the design of the various members composing these tools, especial care was taken to eliminate certain sources of trouble found to exist in the usual type of counterbore. For instance, the pilots of regular tools frequently become loose and when this happens the workmen usually rough up the pilot stem and drive it back into place. Naturally this treatment often causes the pilot to run out of true with the body of the counterbore. Then again many counterbores are broken by the workmen in their efforts to press the pilots in hard enough to make them stay in place. It is the elimination of troubles of this kind that has made the new tools so successful.

TABLE 1. DIMENSIONS OF COUNTERBORES OR SPOT-FACING TOOLS

Machinery

The complete tool consists of a counterbore, a pilot, an adapter ring and shank, as shown in the assembly view that accompanies Table 1. The data in Tables 1 and 2 give the various dimensions of all the parts required in covering a wide range of sizes.

It will be noted that many dimensions of these parts are the same for different sizes. This makes the parts interchangeable and also reduces the total number of parts actually required. These counterbores are comparatively inexpensive to manufacture, as very little tool steel is necessary. The tool can be disassembled easily at any time by simply unscrewing the pilot.

It will be noted that the flutes of the cutter shown in connection with Table 1 follow the path of a right-hand helix, which gives the cutting edges a positive shear. The flutes may, of course, be cut to conform to a left-hand helix, or spiral, when conditions require a cutter having a negative shear. Thread N (see Table 2) is made rather a loose fit for the thread in the shank of the tool. This permits the accurately turned body section M to center the pilot exactly in the cutter.

The most important news in the automobile field has been the \$80,000,000 merger of manufacturers of automobiles, trucks, and parts under the name of the Associated Motor Industries, with factories in seven states.

REMOVING DENTS FROM METALLIC SHELLS

By A. EYLES, Foreman Sheet Metal Worker
Lancashire & Yorkshire Railway, Manchester, England

The article relating to the removal of dents from metallic shells, which appeared on page 101 of October, 1921, MACHINERY, was of great interest to the writer, because removing and straightening out dents in metallic shells, closed cylindrical vessels, automobile lamps, brass musical and scientific instruments, tubing, sheet-metal parts of damaged automobiles, etc., is an important part of the work in the sheet-metal shop where the writer is employed. The following practical hints for removing and straightening out the dents on metallic objects may be of interest to readers employed in various branches of engineering:

In general practice, it is found best to anneal the metal in the immediate vicinity of the damaged part, in order to insure an equal flow and to minimize any possibility of cracking. If the shell or vessel is made from copper, the damaged part should be annealed by being heated to a dull red color, and then instantly plunged into cold water. Copper or brass shells should never be annealed in a freshly made coke fire. The blast should be turned on until the fire is incandescent, as otherwise the sulphur in the coke will affect the quality of the copper. Again, it is not advisable to work thin copper while it is hot. Iron and mild steel shells can be worked on much better when hot, but it may be ruinous to work on copper in a similar manner; this also applies to aluminum, brass, and zinc articles.

Methods of Annealing

Brass shells require very careful annealing in order to prevent the metal from being overheated and becoming brittle. Some kinds of brass will even crumble while in a red hot state if touched with a hammer. As regards the method or rate of cooling brass after it has been annealed (the metal must not be heated above a dull red color) the writer invariably finds that on hard worked or hardened sheet brass, such as is generally used for intricate stampings, spinnings, etc.; the most favorable conditions are obtained when the metal is cooled slowly in the atmosphere.

Aluminum shells require less annealing than brass shells. The metal should be heated to a very dull red color (which is perceptible only in the dark) and then cooled slowly. A suitable annealing temperature varies from 700 to 900 degrees F., depending on the thickness of the metal and the length of time it is subjected to the heat. Metallic shells, etc., made from tin and terne-plates, and electroplated ware cannot be satisfactorily annealed, as their protective coatings will be destroyed by the heat.

Removing Dents from Thin Shells

If the shell is made from very thin sheet metal and if there is no means of working from within, a piece of stout wire should be soldered to the shell in the center of the dent. After the solder has set, the wire can be given a strong pull so that the metal will be pulled outward. The wire can then be melted off. A wire bent to form a handle will be found to be a useful tool for this work, and it can be kept on hand ready for the next job. Sometimes when the dent is not eliminated satisfactorily by this method, a few light blows with a flat-faced bright hammer delivered around the dent will greatly improve the appearance of the piece. If a polished brass article has been dealt with, such as a brass musical or scientific instrument, very fine emery cloth should be used to remove every trace of solder, afterward rottenstone and oil, or tripoli and oil should be used, finishing off with dry powdered lime. Buffing is used, of course, whenever highly polished surfaces are required.

TABLE 2. DIMENSIONS OF COUNTERBORE SHANK, RING, AND PILOT

	Shank							Ring			Pilot		
No.	A	B	C	D	E	F	G	H	J	K	L	M	N
1	3/4	1 1/4	5/16–18	1/4	0.625	0.250	1/8	3/4	0.625	7/16	1 7/8	0.311	5/16–18

19	2	2	9/16–12	3/8	1.499	0.375	3/16	2	1.500	5/8	3 7/16	0.561	9/16–12

Machinery

If the shell has an opening at one side large enough to permit a suitable tool to enter, the dent or bulge can be straightened out by hammering, the projecting dent inside the shell being hammered back by placing the shell on an iron stake and manipulating the hammer so that while the dent rests on the stake the blows will be delivered on each side of it, or around it. Persistent and judicious hammering will force the dent out until the original shape is restored.

Filling up Dents

In some cases it is more economical to load the dent up with solder and smooth it with a file or scraper, and sandpaper, or to solder a patch of metal over the damaged part, after which the soldered part can be filed or ground down until the shell resumes its original appearance. The indented surfaces to be soldered and the adjacent metal must be thoroughly cleaned before attempting to solder. When a patch is employed, it should be held down during the soldering process, say with an old file, which should not be removed until the solder is firmly set. All traces of the flux used for soldering should be thoroughly washed off to avoid subsequent corrosion of the metal.

Removing Dents from Tubing and from Spherical Shells

Another method of eliminating dents in metallic shells of small diameter, such as tubing, etc., is to obtain a number of steel balls, highly polished, and equal in diameter to the inner diameter of that part of the shell or tubing which is undamaged. Anneal the damaged part, as previously explained, and then drive the balls throughout the entire length of the shell or tube. A little powdered black lead sprinkled among the balls in the shell will facilitate the work. Obviously, if the balls can be made to pass through the shell, the latter will be restored to its original shape. If steel balls are not available, hard wooden balls may be used; but these, of course, will not produce as good a job if stout metal is being handled.

Dents on tubing such as used in the manufacture of microscopes, telescopes, etc., can be removed by laying the tube on the surface of a piece of hard wood, and, with either a burnisher or a round piece of hard wood, rubbing the inside of the tube over the indentations, which will quickly bring the indented surface up level.

In some cases, it is possible to remove a dent from a spherical shaped shell by lightly hammering the outer edge of the dent with a smooth-faced hammer until the indentation disappears. The degree of success of this operation will depend, of course, on the thickness and characteristics of the metal, and the skill of the workman. Dents from 6-inch copper floats have been eliminated by this method.

Removing Dents from Car Roofs

The writer has recently been employed in removing dents from the metal roofs of a number of all-metal railway vehicles. The roof material was sheet aluminum, 0.080 inch thick, and the indentations in many cases had a surface of 500 square inches. For this work a hard wood block provided with a handle and shaped to conform with the curved part was used. This block was employed on the inside of the vehicles for forcing the aluminum upward. The dents were removed by carefully manipulating the wooden block and judiciously hammering the metal on the outside of the roof to get the metal to flow from one point to another. To secure a smooth surface and to harden and stiffen the metal, the surface was finished off with a flat-faced bright hammer over a smooth iron tool.

Another unusual job was the straightening out of the dents on a number of aluminum closed cylindrical vessels, 4 feet long by 2 feet in diameter and 0.128 inch thick, with riveted joints and flanges attached. The vessels were badly damaged, and it was therefore necessary to take one of the dish-shaped ends out of the vessel. The dents and buckled parts were easily straightened out with a wooden mallet over an iron stake, after the metal had been annealed well, the surface being smoothed by hammering with a smooth faced hammer.

To make the vessels air-tight again, ¼-inch aluminum rivets of the cup-head type were used, together with a suitable layer of canvas and paint carefully placed between the cylinder portion and the dished end. Sometimes when removing dents from sheet-metal automobile parts, special iron blocks of different radii are necessary. Good results are usually obtained by holding a suitable iron block on the inside and striking on the outside with a flat-faced bright hammer. In all cases, when removing dents from metal surfaces, care must be taken to bring the hammer flat on the face of the work every time, particularly so when smoothing or planishing the metal surface; otherwise, "half-moons" will appear, and it will be impossible to obtain a perfectly smooth and level surface. Success in using the hand hammer in smoothing or planishing metal surfaces can only be acquired by practice, and written instructions are useless without practice.

MAKING JOURNAL BRASSES

By M. E. DUGGAN

When only a few journal brasses of the type shown in Fig. 1 are required it is common practice to make a single pattern from which to produce the castings, but if a large number are to be produced, a double pattern is usually made to permit molding, casting, and machining the brasses in pairs. When a single pattern is employed the pouring is done with the mold lying flat or so that the casting will be in the position indicated by the lower view in the illustration Fig. 1.

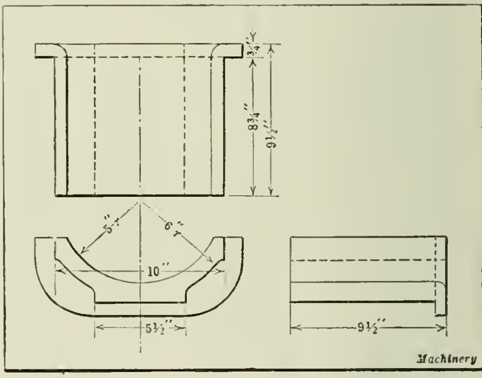

Fig. 1. Journal Brass to be produced

Four different methods of tying or connecting two single patterns to form a double pattern are shown in Fig. 2. In this illustration, corner sections of the four differently constructed patterns are shown grouped about a common center, so that the construction details of the four types can be easily compared. The section of the pattern shown in the upper left-hand corner is attached to the mold board *F*. This type of pattern is objectionable, because when the drag flask with the pattern inside is rolled over and the mold completed ready to draw the pattern, the view is obstructed by the mold board, thus forcing the molder to depend on his sense of feeling when drawing the pattern.

Another objection to this pattern is that the castings produced by its use could not be bored out in the shop without cutting through the tie-sections. In one instance a pattern made in this way was returned to the patternmaker with the request that the tie-piece be so changed that the brasses could be bored in pairs without cutting through the tie-

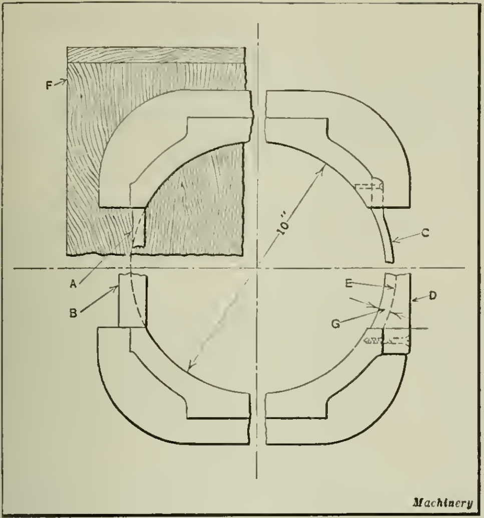

Fig. 2. Four Methods of tying Single Patterns together for casting Journal Brasses in Pairs

pieces. The change was made by simply adding more material to the outside of the tie-pieces, thus increasing the thickness as shown in the lower view at *B*. This method of correcting the pattern was not satisfactory, as it left too much metal to be removed from the brasses by the boring operation.

The pattern shown in the upper right-hand corner is provided with a tie-piece *C* made of finished brass and attached to the wooden pattern by screws. It will be noted that this piece is very thin and that it is made circular in form and set back from the inner surface of the bore slightly so that the boring tool will not touch the tie-pieces when the castings are being bored. The only objection to this method of tying the two single or half patterns together is that the wood-screws will become loosened after a time.

The writer believes that the most satisfactory method of tying the half patterns together is that illustrated in the lower right-hand corner. This method meets every requirement of the molder and machinist. With this type of pattern the two half patterns are connected at each side by hard wood blocks. The lower section of one of these blocks is shown at *D*. They are made flush with the flange and form both the pattern and the core-print. These blocks are carefully fitted to the pattern, and are secured in place with glue and screws. The inner circular surface of the blocks can be made flush with the bore of the pattern or cut back to give clearance for the boring tool. The dry sand core used in this case is made the same shape as block *D* except that its inner surface is cut back as indicated by the dotted line *E* so that the thickness of the tie-piece connecting the two halves of a journal brass casting made from this mold is represented by dimension *G*. In some shops, it is the practice to cut the tie-sections out after the brasses have been bored, and finish machining the parts separately, while in other shops as much of the machining work as possible is performed before cutting the halves apart.

MARCONI RECEIVES JOHN FRITZ MEDAL

The John Fritz medal, one of the highest distinctions bestowed by the engineering profession in this country upon a fellow engineer was awarded to Guglielmo Marconi. the inventor of wireless telegraphy, at a meeting held in the Engineering Societies' Building, New York City, July 6.

LATHE SET-UP FOR VARYING LEAD

By O. S. MARSHALL

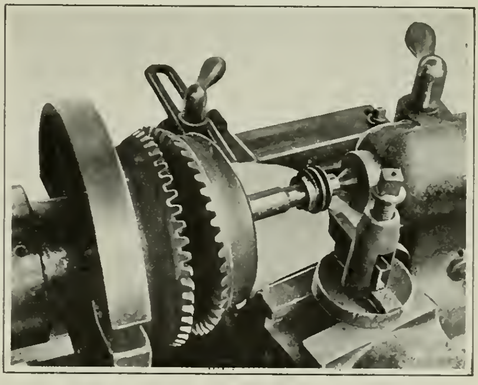
The usual method of obtaining the correct lead when cutting screw or worm threads is to have the right combination of simple or compound gearing between the lathe spindle and the lead-screw. If the occasion arises for cutting some lead for which gears do not happen to be available, it is the usual practice to make or buy one or more gears which will give the required ratio. At least one manufacturer provides his lathe (through the English and the metric gear combinations and an accompanying chart) with a means of cutting a great variety of fractional leads. This is satisfactory where an elaborate equipment is not objectionable. In some cases, however, more simple and less expensive equipment must be used. Then any modern engine lathe provided with a taper-turning attachment will be found to give equally accurate results without the use of other gears than those normally provided.

Cutting Fractional Leads

The necessity of cutting fractional leads frequently occurs in connection with the machining of helical gears having an extreme helix angle which may often approach that of a coarse lead-screw. Such gears may resemble a worm in appearance except for their tooth form. When, as frequently happens, the lead is finer than can be generated on a milling machine, the engine lathe can be used with perfectly satisfactory results. The limit of milling machines in the matter of short leads is generally 0.600 to 0.670 inch. It is inadvisable to undertake anything finer than this on the milling machine, and unless a regular gear-hobbing machine and a suitable hob is in stock—which is improbable—the engine lathe is naturally the machine to use.

A job repeatedly performed on an engine lathe, which is described in the following, will serve to illustrate the method. The work in this instance is a helical gear which is shown mounted on lathe centers in the accompanying illustration. The pitch diameter is 1.652 inches, and the helix or lead 0.3144 inch. The gear is 10 pitch and has one tooth only, of spur gear form. It resembles an ordinary worm, but is calculated strictly according to helical-gear formulas, which require close adherence to the correct angular relationship with the pitch diameters when the center distances are not susceptible of alteration.

The reader must keep clearly in mind the significance of the terms "pitch" and "lead" as applied to helical gears, and not confuse them with similar terms applied to either worms or screws. The helical gear shown in the illustration has the appearance of a worm, as previously mentioned, and it functions like one, but it meshes with another 10-pitch helical gear. This gear has twenty-five teeth and a pitch diameter of 2.534 inches. The helix angle of the 25-



Lathe Set-up for obtaining Variation in Lead tooth gear is 3 degrees 28 minutes, while the helix angle of the single tooth gear to be cut is 86 degrees 32 minutes.

Setting up the Engine Lathe

It is first necessary to determine if the engine lathe will function satisfactorily in performing work for which a milling machine cannot be used because of its limitations in cutting fine leads. The engine lathe is handicapped, however, in the matter of cutting excessively coarse leads. As it is not permissible or good practice to pass a "drunken" thread, it is essential to provide some means of driving the work uniformly throughout every part of its rotation. This is done by the use of a pair of bevel gears, so cut that they will allow a variation of about 5 degrees in their pitch-cone relationship and still operate smoothly when in mesh as shown.

If gears such as those shown are not easily obtainable, a simple plate with six or eight holes drilled to receive driving studs may be attached to the regular driving plate of the lathe. A special flanged arbor provided with corresponding pins is employed to carry the work. The number of driving pins used will depend upon the degree of refinement required in the work. The greater the number of pins used, the more complete will be the elimination of minute inequalities in the lead.

The next step is to determine the lead or helix of the blank and note its nearest approach to some lead which the lathe will cut with its regular gears. The gears selected should give a lead shorter than the one to be cut but as near to that of the required helix as possible. The reason for this will appear in the following: The lead of the helical-gear tooth is 0.3144 inch and is found by the regular formulas for helical gear design. The engineering department ordinarily supplies this detailed information, including the properly calculated angle at which to set the taper attachment.

Referring to the screw plate of the lathe, we find that 3 1/4 threads per inch corresponding to a lead of 0.3077 inch is the nearest approach to the required lead of 0.3144 inch. The angular setting of the taper bar is therefore 11 degrees 51 minutes. The tailstock of the lathe with the center distances adjusted to receive the arbor on which the work is mounted must next be set parallel with the angular setting of the taper guide. An indicator should be used in connection with a straight arbor placed between centers to insure the accuracy of this setting. The compound tool-rest must also be set to approximately the corresponding angle to permit feeding the tool in during the cutting operation, as the regular cross-slide cannot be used for this purpose when the taper attachment is employed.

The reason for gearing the lathe to cut the nearest shorter lead is that by so doing the least possible set-over of the tailstock will be required. In this respect it should be borne in mind that the amount of set-over on a lathe is limited. The shorter the arbor the better, provided it allows sufficient working space. When the lathe is set up as described, and put in operation, a compound movement is imparted to the tool; that is, the lathe carriage is traversed along its fixed pathway, and at the same time the taper attachment serves to control the movement of the tool along another line, as in ordinary taper turning, except that no taper is given the work since the centers of the work-holding arbor are parallel with the angular setting of the taper guide. In other words, the cutting tool travels farther in relation to its work under these conditions than it would without the use of the taper guide, and no set-over of the tailstock. The mechanical conditions are those of the right angle triangle, in which the lathe carriage moves along the base line and the tool along the hypotenuse—conditions which are readily understood by anyone familiar with machine shop practice.

The formula for determining the angular setting of the taper attachment is simple, and is given here for the convenience of those who do not possess the usual handbooks containing this information. If the lead also is desired, it may be found by first multiplying the pitch diameter by 3.1416 and then multiplying this result by the cotangent of the tooth angle. The cosine of the angle to which the taper-turning attachment is set is obtained by dividing the lead for which the lathe is geared by the required lead. After the cosine has been obtained in this way, the corresponding angle is found by referring to a table of trigonometrical functions.

INDUSTRIAL CONDITIONS IN FRANCE

By MACHINERY'S Special Correspondent

Paris, July 10

The industrial situation in France remains rather unsettled. Iron and steel production is greatly below normal; only about one-third of the blast-furnaces are in operation. On the other hand, there is less unemployment than in the past, but work has not been resumed to such an extent that manufacturers are warranted in buying new stocks of raw materials. Briefly, while there is an improvement, it is very slight and it is not steady.

The greatest improvements are noted in the automobile manufacturing field and in the making of radio apparatus—a development largely due to the broadcasting of concert programs from the Eiffel tower. Weather reports are also broadcasted throughout France by means of radio.

Reductions in wages have caused a number of strikes, one of the more important of which is in the metal-working field in the Lille section. This strike was due to a reduction of 25 centimes per hour, and as a result 9000 men went out on strike. In the Havre section a reduction of 10 per cent in wages has caused a strike of 10,000 metal workers. Most of these strikes in the past have ended by an acceptance of the reduced wages, but with a postponement of two or three months in the application of the lower wage rate.

Government statistics indicate that during the first five months of 1922 there was a considerable decrease in the value of imports over the corresponding period of 1921; and the total amount of exports was 378,000,000 francs in excess of the imports.

The machine tool market is very dull. The war stocks and machines generally are in the hands of dealers who are disposing of them only at a very slow rate. Some manufacturers have organized their own sales service to dispose of their excess stocks of machine tools. A few of the machine tool plants are shut down on account of the present difficulties.

Some examples of prices in the small tool field may prove of interest. Carbon steel 10-millimeter twist drills (approximately 3/8 inch) are sold at 4 francs (present exchange, 34 cents); same size, high-speed steel, 8.80 francs (75 cents); one-inch size, 20.90 francs ($1.77) for carbon steel, and 57.50 francs ($4.89) for high-speed steel drills. The two-inch sizes sell at 95 francs ($8.08) and 180 francs ($15.30) respectively.

PRICES OF GERMAN MACHINE TOOLS RISING

A recent letter from a machine tool dealer in Scandinavia indicates that the prices of German machine tools are gradually rising in Germany's foreign markets. This dealer states that these prices have now reached the world price level, and in many instances they are above the prices of machine tools built in other European countries. Scandinavian machine tool dealers now look more hopefully toward the future. While at present all the Scandinavian countries suffer from a severe industrial depression, it is expected that when industrial activity returns, there will be a fair market for machine tools other than those of German make.

QUENCHING SMALL PARTS

By E. B. NICHOLS

Difficulties are frequently encountered in quenching small parts that weigh only a few pounds per hundred pieces. The main problem is to keep the parts properly separated in order to prevent excessive heating of the quenching liquid before it reaches the interior of the mass. The next point is to keep the bath of a uniform temperature so that successive batches or pieces will be cooled at the same rate. The perforations in a basket intended to receive or hold small parts must necessarily be very small. For this reason proper circulation of the liquid is seldom obtained in the usual type of quenching basket. One of the objectionable features of the usual type of basket is that the perforations in the bottom are covered up when the basket receives the first batch of work. Thus instead of coming in contact with the work, the cool incoming liquid is forced to pass around the basket and up the side of the cooling tank to the overflow.

To overcome these difficulties, the special basket in Fig. 1 was designed. This basket was used in a tank in which the cooling medium enters at the bottom from the source of supply at a pressure just sufficient to agitate the liquid at the top of the tank. The liquid then passes through tube *A*, out under the conical shaped head *B* to the top of the basket and over the edges of the tank to the overflow. When the parts are dumped into the basket they must pass through a column of liquid two feet deep which is maintained at a uniform temperature. The mass of parts breaks up on striking cone *B*, and continuing on its way downward meets the incoming liquid from under the cone while it is passing to the bottom of the basket where it comes to rest around the central tube. Uniform temperature conditions are thus maintained so that every part receives the same treatment.

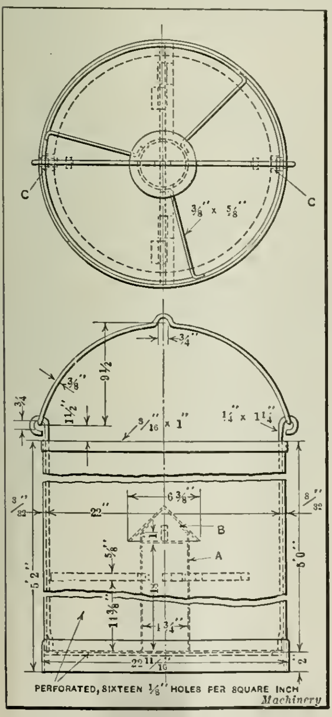

Fig. 1. Sheet-iron Basket for quenching Small Parts

As it would be difficult to remove the contents of this basket in the regular manner, the bottom was made in two halves hinged in the middle and held by latches *C*. The bottom halves swing down when the latches are released.

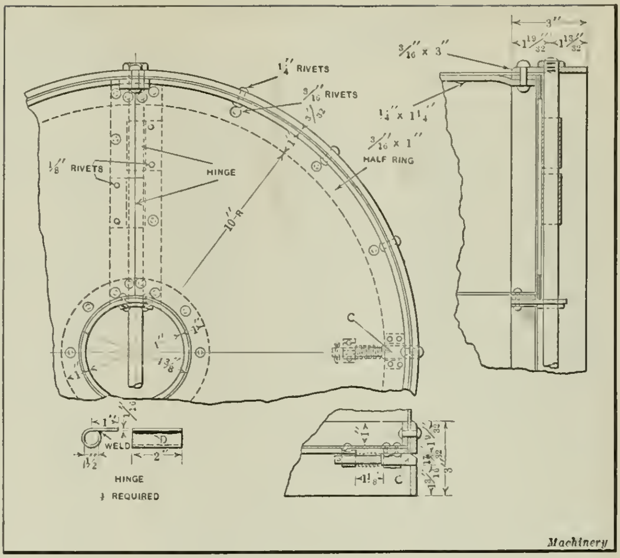

Fig. 2. Details of Hinged Bottom of Basket shown in Fig. 1

Fig. 2 shows the details of the hinges and latches *C*. The latches are made flush with the outside of the basket to prevent them from being accidentally disengaged or damaged by contact with the circulating coils of the tank. A rod placed against the end of the latch and given a light blow forces the latch from engagement with the slot in the side of the basket. This permits the bottom to swing downward so that the quenched parts will drop out.

The hinges for the bottom of the basket are attached by rivets. A detail of one of these hinges is shown in the lower left-hand corner of Fig. 2. The cylindrical part of the hinge is formed by rolling up one end of the flat stock and welding it at *D*. Baskets of this kind have proved very satisfactory and have been in constant use for the last five years.

CONSOLIDATED MACHINE TOOL CORPORATION OF AMERICA

A news item in July MACHINERY mentioned the formation of the Consolidated Machine Tool Corporation of America through a combination of the Newton Machine Tool Works, Inc., Philadelphia, Pa.; Hilles & Jones, Wilmington, Del.; Betts Machine Co., Rochester, N. Y.; Colburn Machine Tool Co., Cleveland, Ohio; and Modern Tool Co., Erie, Pa. To this list has been added the Dale Machinery Co., Inc., New York and Chicago; and the Ingle Machine Co., Rochester.

Officers of the corporation have also now been chosen. W. H. Marshall, formerly president of the American Locomotive Co., is chairman of the board of directors; C. K. Lassiter formerly vice-president of the American Locomotive Co. is president. The vice-presidents are H. J. Bailey, president of the Hilles & Jones Co.; H. W. Breckenridge, vice-president of the Colburn Machine Tool Co.; H. W. Champion, president of the Newton Machine Tool Works, Inc.; J. J. Dale, president of the Dale Machinery Co.; and A. H. Ingle, president of the Betts Machine Co. and the Ingle Machine Co. O. D. Miller is treasurer of the new corporation and R. R. Lassiter, secretary.

The board of directors includes, besides W. H. Marshall, chairman, C. K. Lassiter, H. J. Bailey, B. J. Baker, H. W. Breckenridge, Lawrence Chamberlain, H. W. Champion, J. J. Dale, T. Allen Hilles, A. H. Ingle, and F. D. Payne. The general offices are at 17 E. 42nd St., New York City.

STUDY MAKES MORE EFFICIENT MECHANICS

By JIM HENDERSON

No mechanic will ever attain a high state of proficiency if he neglects to acquire and retain those rudiments of arithmetic that are essential to a more thorough understanding of the fundamentals of mechanical engineering. Too many workmen of today are apparently content with the limited knowledge required to enable them to perform the actual operations of cutting metal to bring a piece of material to the specified shape and dimensions. Without the application of mathematics the study of engineering would be virtually impossible, and without a fair knowledge of the first principles of arithmetic, even the simplest mechanical operations would be difficult to perform. Many men fail to realize the importance of acquiring the technical or theoretical principles of mechanics as a means of simplifying the solution of their shop problems. The fact that a boy has been able to obtain only a limited public school education should not deter him from aspiring to a more thorough knowledge of the science upon which his work is based.

It is probably true that modern methods of manufacture often eliminate the necessity for the workman to use the learning of his younger days in the production of the work upon which he is engaged. This condition, however, must be accepted and must be recognized by every workman as one that will gradually place the machine tool operator in a position relatively the same as any part of the machine that he is called upon to serve. The actual thinking and planning of his duties is becoming a problem in the solution of which the workman has little to do, owing to the so-called "efficiency methods" that are constantly being adopted in mechanical industries. These systems, however, unless operated on a comprehensive cooperative basis, must eventually crush the individual initiative in factory employes, so that their tasks become more a subject of observation and application than the concentration of reasoning powers for successful achievement. It is obvious, therefore, that if a workman aspires to a higher position, where his brain will relieve his hands of the labors of former days, he must acquire the knowledge that will enable him to apply these potential but often dormant faculties.

Many young men, and not a few that are advanced in years, refrain from the study of technical journals or handbooks because of the general use of formulas in such textbooks, believing that a comprehensive knowledge of algebra is required before these formulas can be used. A brief study of a formula will demonstrate to the average mechanic that the only requirement is a well grounded learning in the elementary principles of arithmetic and a patient application of these fundamental rules. Of course, there are many formulas that necessitate a wider knowledge of mathematics than those possessed by ordinary mechanics, but persistent study and practice in working out the simpler problems will gradually develop the reasoning powers to such an extent that, eventually, the difficulties will not appear so formidable.

To achieve, one must continue to strive, as the prize is invariably given to the winner, and in these days of rapid progress and development no man can hope to succeed and at the same time be content to sit still and let the boat drift with the tide. Seldom does the current flow in the right direction, and in order to reach a haven where the "going" requires less effort, it is necessary to get out the oars and pull against the stream, and the harder you pull the sooner you will be in a position to watch the others as they drift indifferently or struggle to free themselves from undesirable though oftentimes unavoidable environment.

Many men today are wasting their time and energies in commenting on the other fellow's job—a factor that cannot but detract from the ability to do justice to their own. Those men who are continually envying the other fellow and his "soft job" will rarely ever find themselves in a similar position, as with few exceptions these so-called "soft jobs" are the result of previous concentration, study, and hard work. Therefore, it is imperative, and also quite obvious, that the ambitious young mechanic who hopes for greater remuneration or a more responsible position, must use every means to fit himself for the wider duties that call for a thorough knowledge of the work upon which he is temporarily engaged, together with the fuller technical understanding that is essential to the successful filling of the job higher up.

COOPERATION IN STANDARDIZATION

The Division of Simplified Practice has been established by Mr. Hoover in the Department of Commerce with a view to cooperating with manufacturers and engineering societies in engineering standardization work. The American Society of Mechanical Engineers and the American Engineering Standards Committee are among the engineering bodies cooperating with the Department of Commerce in this work. It is not the intention of the Division of Simplified Practice to duplicate the engineering standardization work now being done through the agency of the American Engineering Standards Committee, but to develop a special field of broad usefulness by reducing the number of sizes and by simplifying the varieties of manufactured articles in common use. Secretary Hoover has invited the cooperation of all engineering and trade societies for determining what simplification in manufactured products is most needed and most desired at this time. Members of engineering societies who have suggestions with regard to simplifying the varieties of manufactured articles in common use, or the standardization of sizes in general for manufactured articles, are requested to communicate with either the Division of Simplified Practice of the Department of Commerce, Washington, D. C., or the American Engineering Standards Committee, 29 W. 39th St., New York City.

STATISTICS OF THE MACHINE TOOL INDUSTRY

The accompanying tables have been prepared from statistics compiled by the Bureau of Census of the Department of Commerce. Table 1 shows the distribution of the machine tool industry in the different states in 1919, the percentages given being based on the value of the product of the machine tool shops in each state. It will be seen from this table that Ohio produces nearly 30 per cent of the machine tools in the country. The New England states together produce nearly 35 per cent, Massachusetts and Rhode Island leading, with Connecticut a close third. The three states, Ohio, Massachusetts, and Rhode Island produced in 1919 over one-half of the machine tools built in the country.

TABLE 1. DISTRIBUTION OF MACHINE TOOL INDUSTRY IN DIFFERENT STATES IN 1919, BASED ON THE VALUE OF THE PRODUCT

State	Per Cent	State	Per Cent
Ohio	29.5	Delaware	1.200
Massachusetts	11.0	Kentucky	0.500
Rhode Island	10.5	Minnesota	0.400
Connecticut	8.7	Maryland	0.300
Pennsylvania	7.9	Missouri	0.210
Illinois	7.1	New Hampshire	0.110
Michigan	6.0	California	0.036
Vermont	4.5	Washington	0.031
Wisconsin	4.4	Maine	0.008
New Jersey	3.2	Iowa	0.004
New York	2.4	Kansas	0.001
Indiana	2.0	United States	100.000

Machinery

TABLE 2. VALUE OF PLANTS AND PRODUCT OF THE MACHINE TOOL INDUSTRY IN 1919

State	Number of Plants	Value of Land, Buildings, and Equipment	Taxes Paid	Cost of Materials	Cost of Fuel and Power	Value of Product	Value Added by Manufacture
Ohio	102	$56,626,865	$6,294,723	$16,731,367	$745,468	$62,554,169	$45,077,334
Massachusetts	46	32,446,551	1,072,132	6,532,701	376,062	23,442,547	16,533,784
Rhode Island	13	25,036,802	1,723,094	3,368,170	325,796	22,301,290	18,607,324
Connecticut	33	20,380,557	1,040,390	4,548,245	374,721	18,435,449	13,512,483
Pennsylvania	32	21,869,376	1,967,759	4,516,253	251,782	16,797,040	12,029,005
Illinois	28	14,323,537	593,090	4,582,312	173,097	15,008,096	10,252,687
Michigan	31	14,438,803	619,855	3,789,355	182,818	12,656,492	8,684,319
Vermont	6	11,041,881	1,434,642	2,817,119	110,016	9,609,745	6,682,610
Wisconsin	24	10,865,674	1,044,683	2,456,188	142,270	9,414,820	6,816,362
New Jersey	14	7,343,687	936,220	2,345,341	75,241	6,767,671	4,347,089
New York	29	7,351,076	306,956	1,231,764	73,181	5,027,880	3,722,935
Indiana	15	4,315,557	206,788	1,303,228	71,107	4,259,463	2,885,128
All other states	30	4,999,477	598,570	1,826,291	84,415	6,125,496	4,214,790
United States	403	231,039,843	17,838,902	56,048,334	2,985,974	212,400,158	153,365,850

Machinery

Table 2 shows that the value of the land, buildings, and equipment of the plants engaged in machine tool manufacture in the United States was about $231,000,000, and that the total value of the product was $212,000,000. The machine tool industry in that year paid nearly $18,000,000 in taxes.

Table 3 shows that nearly $75,000,000 was paid in wages to office and shop employes, and $9,500,000 in salaries to officials. The total number of people engaged in the machine tool industry was nearly 62,000.

TABLE 3. NUMBER OF EMPLOYES, SALARIES AND WAGES IN MACHINE TOOL INDUSTRY IN 1919

State	Number of Plants	Persons Engaged in the Industry					Salaries and Wages		
		Proprietors and Firm Members	Salaried Officers Superintendents, and Managers	Office Employes	Average Shop Employes	Total	Officials	Office Employes	Shop Employes
Ohio	102	29	663	1565	13,855	16,112	$2,511,242	$2,028,768	$17,071,620

All other states	30	21	71	118	1,132	1,342	331,963	156,585	1,472,681
United States	403	132	2333	6186	53,111	61,762	9,491,952	8,545,904	66,178,969

Machinery

Table 4 shows a comparison of the sizes of machine tool building plants in 1919. This table shows that 13 per cent of the number of plants (representing the largest shops) produced 69 per cent of the product, while 45 per cent of the plants (representing the smallest) produced only 3 per cent of the product. The total number of shops was 403.

This is the first time that statistics as complete as these have been compiled for the machine tool industry, and the Bureau of Census has performed a valuable service in preparing a complete record of the important facts relating to this basic industry.

SAFETY CODE FOR FOUNDRIES

The American Engineering Standards Committee has approved a national safety code for the protection of industrial workers in foundries. This code is a revision of that developed by the American Foundrymen's Association and the National Founders' Association who are joint sponsors of the new code. The code has been worked out by a committee composed of four representatives of makers of foundry equipment and owners of foundries, four governmental bodies, two technical societies two insurance organizations, and a representative of foundry employes. Copies of the code may be obtained from the American Engineering Standards Committee, 29 W. 39th St., New York City.

The American Engineering Standards Committee has also approved a national electrical safety code as proposed by the Bureau of Standards, which covers the generation, distribution and utilization of electricity for power, light and communication. It constitutes one of the most important steps yet taken in safeguarding electrical installations.

TABLE 4. COMPARATIVE SIZES OF MACHINE TOOL BUILDING PLANTS IN 1919

Value of Lands, Buildings and Equipment	Number of Shops	Total Number of Shop Employes	Number of Employes per Shop	Value of Product	Product per Employe	Average Value of Product per Shop	Per Cent of Total Value of Product in Industry
Over $1,000,000	52	35,525	683	$146,142,000	$4100	$2,310,000	69
$500,000 to $1,000,000	41	7,235	176	27,856,000	3869	679,000	13
$100,000 to $500,000	134	8,162	62	31,760,000	3873	238,000	15
Less than $100,000	176	2,186	12	6,642,000	3030	38,000	3
Total of all shops	403	53,111	132	212,400,000	4000	531,000	100

Machinery

The Machine Tool Industry

THE improvement in the machine tool industry, although slight, is none the less definite. The average orders of seventy-nine firms in this field, during the month of June, amounted to 25 per cent of the shipments for the first three months in 1920—the period which had been taken as a standard for purposes of comparison. Seven of these firms reported a business of over 50 per cent; and eighteen, or about one-fourth of the number, of over thirty per cent. These comparisons are made on a dollars and cents basis. When the lower prices of machine tools at the present time are considered, it is evident that the actual volume of machines sold reaches higher percentages than those mentioned.

There is a great difference in the activity, however, according to the line of machines being built. Grinding machines are among the types in greater demand than most other lines. There has also been a good market for small automatic screw machines due to the activity in the radio field, but this demand is now falling off somewhat. Orders for special machines for high production are in evidence to a greater extent than orders for standard lines of machine tools; the automobile industry has been largely responsible for this. Service stations and garages have also been among the important customers of the machine tool industry. The automobile repair shop business has also afforded an outlet for a considerable part of the second-hand machine tools that have been on the market.

One of the encouraging signs is the brisk demand for grinding wheels, indicating that the metal-working industry as a whole is resuming its activity. Some grinding wheel plants state that the demand is much above the pre-war figure, and in one instance, at least, the plant is running at full capacity.

In the special machinery field business is fairly active, some shops in this class being occupied at approximately 60 per cent of their capacity. Most of the business in this field is domestic, but some orders are being booked from Japan, Australia, and South America. The trade with Europe is small, although recently some special machinery has been ordered from England.

Generally speaking, the conditions in the machine tool and accessories field are somewhat less active in New England than in the middle western states, due, no doubt, to the proximity of the latter to the automobile industry. In New England, second-hand machinery is still in greater demand than new machines, whereas a Cleveland dealer states that the tide has turned in that district and that new machines are sold in excess of used equipment. One of the main difficulties with which machine tool builders have to contend is the spotted condition of business, one month being quite good and giving a fair promise of continually increasing business, while during the following month business falls off, keeping the average for the year down. The greatest activity is naturally noted in the plants directly or indirectly supplying the automobile shops. Plants so engaged are frequently running to capacity, and a few are even farming out part of their work.

Prices of Machine Tools

Several machine tool manufacturers have announced increases in their prices, and it is expected that there will be a general advance in machine tool prices. The reductions that have been made during the past eighteen months are entirely too great to remain permanently in effect. Labor rates and material costs have not been sufficiently reduced to warrant the prices that have been quoted—prices that in many instances were quite far below replacement costs.

General Activities in the Machine Shop Field

The screw products shops are well occupied. A few months ago very low prices were quoted for screw products, but this condition is now improving. The sheet metal stamping shops in the Middle West are generally fully occupied; in New England, they are running at from 50 to 80 per cent.

Several machine tool builders who have embarked upon the manufacture of other lines of machinery in order to divert some of their shop capacity have been quite successful in their new ventures. Among the products that are thus turned out in machine tool plants are road-building machines, concrete block machines, domestic washing machines, auxiliary steam turbines, electric fans, and air conditioners. The interest in road-building throughout the country has created great activity among manufacturers of this line of machinery, and makers of excavating machines and steam shovels are fully occupied.

In the small tool field the conditions are gradually improving, even if not so rapidly as was at one time believed would be the case. Most of the manufacturers of small tools are working at from 30 to 40 per cent capacity. Practically the same condition exists in the measuring tools.

Conditions in the Gear-cutting Shops

Gear-cutting shops in the Pittsburg district operate at from 40 to 50 per cent capacity, but competition makes it difficult to obtain a satisfactory price for the product. This refers to shops engaged in general gear-cutting, rolling mill gears, and mine gearing. The shops devoted to automobile gears are running to capacity, and some are said to have difficulty in meeting the demand for early deliveries. In the Cleveland district the shops employed in general job work run from about 40 to 70 per cent capacity. Gearing for heavy machinery is beginning to be ordered again, indicating increased business of heavy machinery builders.

The Automobile Industry

In the automobile field the past three months have shown an unusual activity. In May over 231,000 passenger cars and nearly 25,000 trucks were built. The figures for June were, in round numbers, 240,000 and 30,000 respectively; and while there was some decrease in the July production schedules of passenger cars, the drop was not more than 20 per cent, while the production of trucks increased.

The continued demand for automobiles has revealed an unexpected purchasing power on the part of the general public, and some makers have found it impossible to supply their dealers immediately with cars to meet the demand. Ford production naturally has led all the rest with considerably over 100,000 cars a month for several months. The total production of passenger cars for the first six months of the year is about 1,100,000, and of trucks, about 120,000. There are at present 177 manufacturers of passenger cars in the United States and 230 manufacturers of motor trucks.

The Studebaker plants have been working to capacity for some time past. Plans for a considerable increase in machining equipment and output are under way. It is said that when the plans now laid have been consumated, the Studebaker South Bend plant will be capable of producing 500 cars a day. This will, of course, require a large amount of machine tools, some of which are now being bought.

New Machinery and Tools

The Complete Monthly Record of New American Metal-working Machinery

The New Tool descriptions in MACHINERY are restricted to the special field the journal covers—machine tools and accessories and other machine shop equipment. The editorial policy is to describe the machine or accessory so as to give the technical reader a definite idea of the design, construction, and function of the machine, of the mechanical principles involved, and of its application.

Liberty Combination Planer and Slotter

PLANING and slotting operations on locomotive frames are usually cumbersome jobs because of the size of the work and the necessity of setting up the work on both a planer and a slotter or shaper for the performance of the operations. The time consumed in making one of these set-ups is eliminated with the combination planer and slotter presented in the accompanying illustration. This machine has recently been developed by the Liberty Machine Tool Co., Hamilton, Ohio. Another advantage of this machine is the saving of floor space, this being an important factor owing to the size of the machines necessary for handling work of this class. The machine has two cross-rails near the middle of the bed; one supports a planer head and the other carries a slotter head. The cross-rail for the slotter head can be swiveled entirely out of the way when the machine is being used for planing work that requires the raising of the planer cross-rail to its highest position. The machine has a duplex control by means of which the different moving parts may be operated from either side of the bed. The planer and slotter units are individually motor-driven. Although the machine was designed primarily for finishing locomotive frames, it is adaptable to other jobs.

Construction of the Planer Unit

The parts embodied in the planer unit are identical to similar parts included in the standard 36-inch planer built by

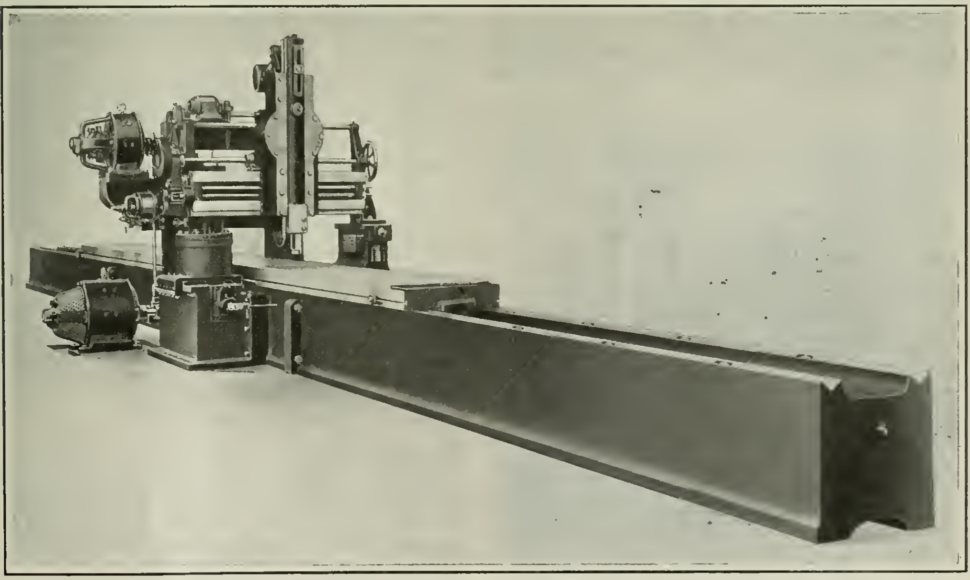

Fig. 1. Liberty Combination Planer and Slotter developed to reduce the Machining Time of Locomotive Frames

the same company. This unit is arranged with a reversing motor-drive, which gives the necessary range of speeds. Although only one head is shown on the cross-rail, two may be furnished on this member, and side-heads may also be provided on the housing faces. The bed is of box construction and has a closed top between the vees. The latter are fitted with automatic oiling rollers to insure proper lubrication of the bearing surfaces.

The rollers may be readily removed to facilitate the cleaning of pockets. The table T-slots are planed for the solid, and the holes provided for clamping work on the table are reamed. The cross-rail is of sufficient length to allow two heads to have a full traverse across the table. The cross-rail elevating screws are supported on ball bearings and are adjustable from the top.

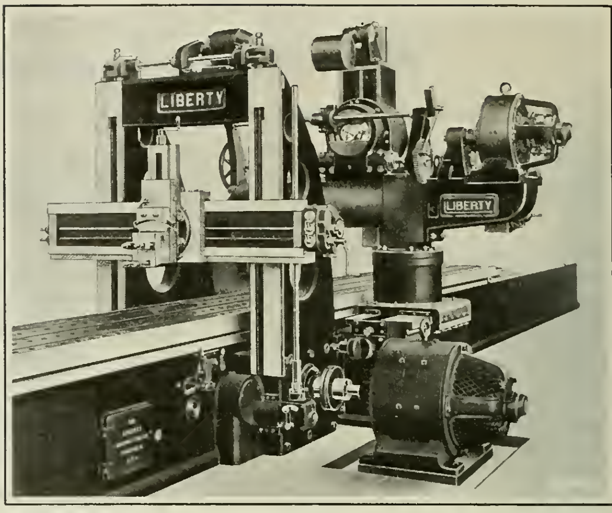

Fig. 2. Close-up View showing Front of Planer Unit and Back of Slotter Unit

The heads are made right- and left-hand for close range, and may be swiveled to any position up to 90 degrees, graduations indicating the angularity of a setting. The heads have automatic feeds in all directions, which are operative from either end of the cross-rail. Micrometer adjustments are provided on all vertical and horizontal feed-screws. The cross-rail elevating mechanism is located on the top brace and is controlled by means of a long handle at the side of the housing. This handle is employed to engage or disengage a saw-tooth clutch when raising or lowering the cross-rail. The handle must be held in order to keep the mechanism in operation and, therefore, any obstruction interfering with a movement of the cross-rail will cause the clutch to be instantly disengaged, thereby avoiding any breakage of parts.

When side-heads are attached to the housings, they can be moved to a position below the top of the table when not in use. Patented feed micrometer collars and control handles are conveniently located on these heads and they may also be swiveled through an arc of 90 degrees. This planer has a patented feeding arrangement by means of which the operator can control or change the rate of feed of the cross-rail heads without stopping the machine or disturbing the feeds of either side-head. Similarly, he can change the rate of feed of the side-heads without disturbing the rate of feed of the cross-rail heads. Feeding movements may take place either on the cutting or on the return stroke. All feeds may be disengaged by placing a handle in a neutral position.

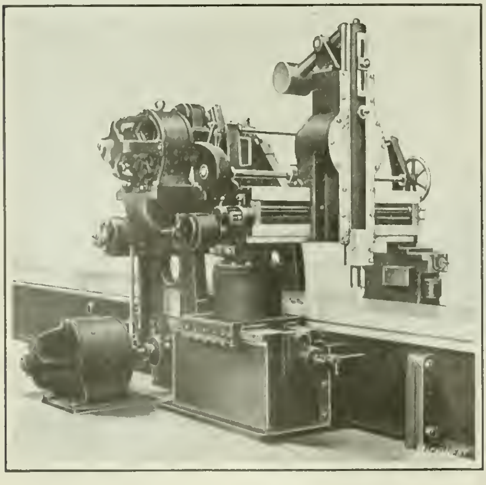

Fig. 3. Illustration in which the Details of the Slotter Unit may be clearly seen

The Slotter Features

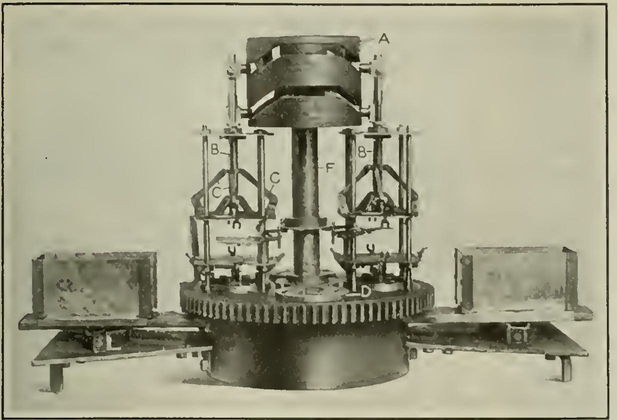
The slotter unit is driven by a variable-speed motor which gives the necessary range of speeds to the ram. Two additional small motors provide power for quickly moving the cross-rail and the ram head. This unit has a 24-inch travel lengthwise relative to the machine, for which movement there is an automatic feed and rapid traverse in both directions. One end of the cross-rail is mounted on a column upon which it may be swiveled, by the rotation of a screw, either forward or backward along the bed to any angle within the limits of locomotive frame work. Clamps provide for holding the cross-rail securely in any angular setting. As previously mentioned, the cross-rail can also be swiveled entirely out of the way to permit the use of the planer unit for machining high work.

The ram head has an independent automatic feed and a rapid traverse in both directions. The ram is driven by worm gearing through a crank disk and connecting-rod, and is properly counterbalanced. The stroke is adjustable for both position and length. A special tool-bar is provided for circular feeding and for machining fillets. The table of the machine is held stationary when using the slotter unit, and is rapidly advanced to the next position after a cut has been completed, by the operation of a pendant switch.

Some of the principal dimensions of the machine are as follows: Maximum width between planer housings, 37 inches; maximum height under planer cross-rail, 37 inches; length of table, 38 feet; width of table, 30 inches; length of bed, 69 feet; miximum stroke of slotter ram, 14 inches; and maximum travel of slotter cross-rail, 24 inches. The weight of the machine is approximately 69,000 pounds.

W-J AUTOMATIC DIE-CASTING MACHINE

An automatic die-casting machine of a continuous rotary type which has been developed by the W-J Die Casting Machine Co., 1120 Marshall Field Annex, Chicago, Ill., to effect increased production rates in the manufacture of die-castings, is here illustrated. This machine consists of a rotating table on which are mounted four sets of cages which carry dies of any required form. Diametrically opposed to each



W-J Automatic Die-casting Machine developed to permit High Rates of Production

other are two melting pots from which a charge of molten metal is delivered to each die as it passes either pot. It will thus be apparent that two castings are produced in each of the four dies during each revolution of the table, or, in other words, eight castings per table revolution. The machine can be driven at the rate of two revolutions per minute, and at this speed, a production of 960 castings per hour will be obtained. At the time the photograph was taken, the melting pots were not in place in their cases on the slides which extend from the machine base, the die-carrying cages and their auxiliary mechanisms had been removed from two of the table stations, and the dies were not in place on the cages shown.

As each station of the table approaches one of the melting pots, the die members at that station are automatically closed and the melting pot advanced to them. A nozzle on the pot enters a socket on the die, after which the necessary amount of metal to fill the die is forced into it either by compressed air or by the action of a plunger. The melting pot then recedes, the die opens, and such core-pins as may be required, withdraw. A knock-out pin next pushes the casting from the upper die member, so that it falls on a tray that is automatically brought into position beneath it. As the table continues its rotation, a pair of revolving brushes passes between the die members and loosens any particles of dirt adhering to them. Finally, a jet of compressed air is blown on the die members to remove any foreign matter that may still remain on their faces. By this time the die cage approaches the second melting pot, and the cycle of movements which occurs is similar to that outlined.

As previously mentioned, each set of dies consists of two members, the upper one of which is movable and the lower stationary. The closing of the upper members on the lower ones preparatory to casting a part is accomplished through cam *A* which has two grooves around its periphery. Rollers which run in the upper grooves are secured to rods attached to the upper dies, and as a die set approaches either of the two melting pots its roller runs down a decline in the groove and causes the upper die to be pushed down upon the lower one. Simultaneously, the roller in the lower groove runs down a decline somewhat longer than that on the upper groove. This roller is secured to a sleeve *B* which in turn is connected to a link mechanism that provides for pushing core-pins into the four sides of the upper die. If vertical core-pins are required, they are pushed straight down through the die. The amount that each core-pin is advanced into the die may be adjusted.

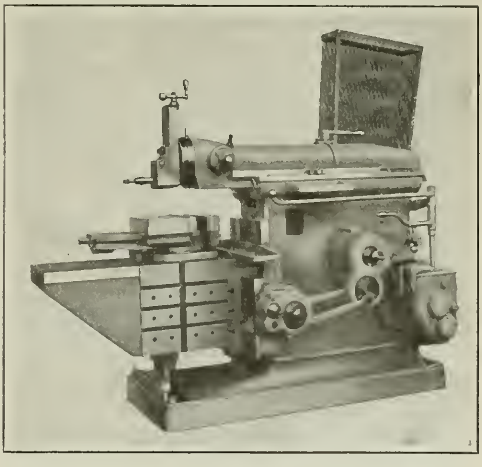
Provision is also made for introducing core-pins into the lower die member. Mounted at each of the four table stations is a plate cam *D* in which four spiral grooves are machined. Each of the cams is carried on a stem that projects through the table and carries a lever. As the table rotates, this lever strikes a dog which causes rotation of the cam. The pins which run in the cam grooves have their lower ends guided by straight grooves, and as each pair of pins slides in its groove, a link is rocked to push a core-pin into the lower die. There are four sets of rocking links to provide for introducing a core-pin into the four sides of this die.

After either melting pot has been advanced to a die, it rotates with it a sufficient length of time, after the nozzle of the pot has been properly inserted, to allow enough metal to be forced into the die. Thus it will be evident that the mechanism which actuates the melting pots must furnish a combined rotary and in-and-out movement.

For shops handling a moderate volume of work, a machine can be built with one melting pot and two sets of dies, or the machine illustrated can be provided with only one melting pot and two sets of dies. An important feature of this machine is that different castings may be produced at the same time by having suitable dies in the cages. Water is circulated continuously through the dies to keep them at the proper temperature. Gas jets heat the metal in the pots and maintain it at the desired temperature. Other gas flames preheat the compressed air which forces the molten metal into the dies. When a plunger and a cylinder are used for this purpose, these parts are also heated by gas flames to prevent solidifying the metal in the cylinder.

HENDEY CRANK SHAPER

A crank shaper equipped with a speed gear-box to permit a single-pulley or constant-speed motor drive has been recently introduced on the market by the Hendey Machine Co., Torrington, Conn. Except for the gear-box this machine is of the same general design as the cone-pulley shaper previously described in MACHINERY. Eight strokes ranging in geometrical progression from 6 to 102 per minute are obtainable, four of these speeds being secured through the gear-box,



Hendey 24-inch Crank Shaper equipped with a Speed Gear-box and four by means of back-gears. The speed box gears run in oil, and the driving and gear shafts in ball bearings. The gears of the gear-box are shifted by the manipulation of a ball handle lever about H-slots in the gear-box cover. The speed gears are made of alloy steel and are heat-treated. The length of ram stroke may be varied from 2 to 24 inches.

The driving pulley transmits power to the machine through a patented clutch which also serves as a brake when moved in the opposite direction to that in which it is shifted for driving. This clutch is controlled by the long horizontal lever which extends to the front of the machine on the right-hand side. The lever has a short movement which provides a quick starting and stopping feature to the ram that is especially of value in setting tools and taking measurements. The lever control also simplifies the meshing of the back-gears and the manipulation of the gear-box lever.

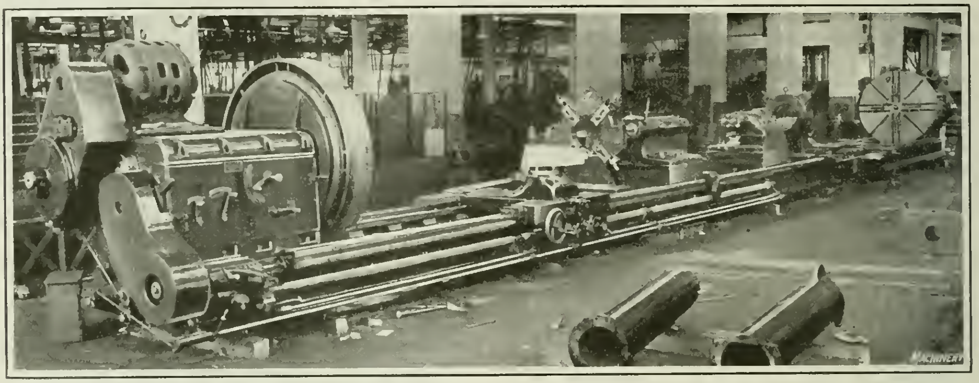
All adjustments of the patented cross-feed mechanism are obtained at the end of the cross-rail. The amount of feed can be varied while the machine is in motion, a dial indicator showing the amount of feed. The feed can be started, stopped, or reversed while the machine is in operation. The feeding movement takes place on the reverse stroke of the machine. The cross-feed screw is provided with a dial graduated in thousandths of an inch. The machine may be furnished with or without a power down-feed by means of which the machine may be fed at any rate from 0.005 to 0.060 inch per stroke, in increments of 0.005 inch. The machine is set for the different rates of feed by means of a graduated dial. Some of the important specifications of the machine are as follows: Horizontal table travel, 30 inches; vertical table travel, 14¾ inches; minimum distance from ram to table, 4 inches; dimensions of table top, 17 by 24 inches or 17 by 42 inches when equipped with an extension as illustrated; dimensions of table side, 17½ by 18 inches; and approximate weight of machine, 5700 pounds.

BETTS-BRIDGEFORD DOUBLE-HEAD ENGINE LATHE

In shops where large machines are installed for handling heavy work, such equipment frequently remains idle a great part of the time, owing to the unsuitability of the machine for handling smaller work. In bringing out the double-head engine lathe here illustrated, the Betts Machine Co., 400 Blossom Road, Rochester, N. Y., has provided the machine with two heads, two carriages and two tailstocks, so that when the entire length of the machine is not required for a job, the two ends may be operated as individual machines. This lathe has a lead-screw on each side of the bed; one lead-screw extends the entire length of the machine and the other is one-half that length. From this it will be obvious that the two carriages are fed from opposite sides of the bed. This lathe was primarily designed for turning heavy crankshafts and long propeller shafts. It has a swing of 72 inches and a bed length of 76 feet.

When the lathe is required for long work, one of the tailstocks is removed from the bed and the other is traversed to a position close to the headstock opposite the one with which this tailstock is employed. By doing this, the maximum distance between centers may be utilized. When the machine is required for shorter work which can be accommodated in somewhat less than one-half the maximum distance between centers, the second tailstock is replaced on the bed end to end with the first after the latter has been traversed approximately to the middle of the bed. In this way the machine is quickly converted into two entirely independent lathes each having a swing of 72 inches and a maximum distance between centers of 27 feet. As the machine is readily convertible from a long lathe into two shorter lathes or vice versa, it will be seen that economies of floor space may be effected.

The headstocks are alike in construction, being triple back-geared and provided with bronze bearings throughout. These bearings are chain-oiled from individual reservoirs. Twelve spindle speeds in geometrical progression are controlled by levers conveniently located at the front of the headstocks. These speeds are obtained through sliding hardened steel gears. A friction clutch and brake is incorporated in the driving mechanism of each headstock and operated from its respective carriage thus allowing the machine to be started or stopped instantly. In addition to the lever on the carriage, a secondary lever on the headstock supplies a means of operating this clutch and brake. A power rapid traverse is provided for both carriages and this is controlled by levers on the aprons. The aprons are of a double-wall construction and the gears are of steel. The machine is driven by two 50-horsepower motors mounted on the headstocks and controlled by automatic starters.



Betts-Bridgeford Double-head Engine Lathe which may be operated as One Long Machine with a Carriage and Tailstock removed, or as Two Individual Machines with these Members in Place

PRATT & WHITNEY ODONTOMETERS

An instrument known as the "Odontometer," manufactured by the Pratt & Whitney Co., Hartford, Conn., for testing the accuracy or uniformity of gear tooth profiles and spacings of the teeth in production work, was described in MACHINERY for July, 1921. This company has now announced a number of improvements in the design of the instrument, and are placing on the market two additional odontometers for testing larger and smaller gears. The original instrument was for use with gears from 3 to 10 diametral pitch, whereas the instrument shown in Fig. 1

Fig. 1. Pratt & Whitney Odontometer for testing Spur and Helical Gears from ¾ to 4 Diametral Pitch

covers a range of from ¾ to 4 diametral pitch and that in Fig. 2. from 10 to 24 diametral pitch. The latter odontometer and that illustrated in the previous article may both be provided with stands to facilitate the testing of gears or pinion-shaped cutters. When either instrument is thus mounted, the gear is placed on the surface plate on the post of the stand and is rolled past the instrument. The actual cutting edge of cutters is tested so that errors of any nature are detected.

The principle upon which the new odontometers are based, is the same as that of the instrument previously described. In effect an odontometer is composed of a section of a straight-sided rack having two parallel effective faces, one fixed and the other movable. A third face, set at an angle to the two working faces, is used to hold the fixed working face in contact with the flank of the gear tooth. The fixed registering surface is at *A*, Fig. 1, and the movable indicating surface at *B*. The third surface *C* holds surface *A* in contact with the involute profile of the gear tooth. Surfaces *B* and *C* are adjustable so that gears of various pitches can be tested with the same instrument. The indicating surface *B* is mounted on two thin flat springs *D*, which act as pivots, free from backlash. The dial indicator is actuated by a lever having a ratio of 5 to 1, each division of the dial representing a movement of 0.0002 inch of surface *B*. The instrument is used to test the uniformity of mating gears.

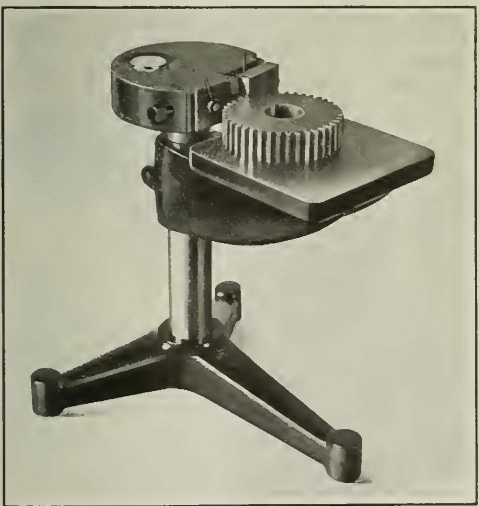


Fig. 2. Odontometer for Gears from 10 to 24 Diametral Pitch

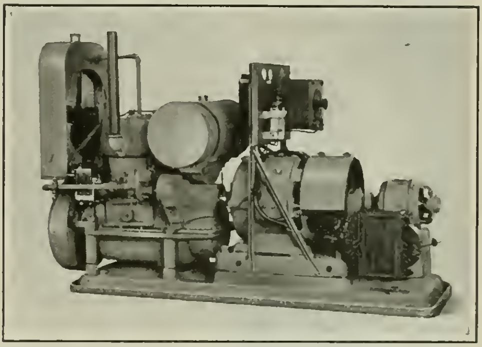
WESTINGHOUSE GASOLINE-DRIVEN WELDING EQUIPMENT

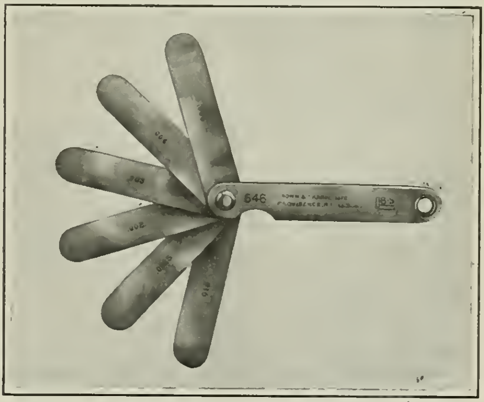
A welding equipment developed for use where electric power is not available for driving a motor has been placed on the market by the Westinghouse Electric & Mfg. Co., East Pittsburg, Pa. This equipment is made in both stationary and portable models. It consists essentially of a Westinghouse single-operator direct-current welding generator geared to a Doman 4-cycle, 2-cylinder, low-speed, marine-type gasoline engine. The generator has a rated capacity of 175 amperes and a maximum capacity of 225 amperes, at 1750 revolutions per minute. It is designed to operate at arc voltage and to inherently stabilize the arc and supply a substantially constant current of different values over the working range of 90 to 225 amperes. It is said to be easy for the operator to strike and maintain the arc and to obtain the deep penetration and thorough fusion necessary for satisfactory welding. The shaft of the generator is attached to the exciter by means of a flexible coupling. The control panel is mounted directly over the generator.



Westinghouse Welding Apparatus driven by a Gasoline Engine

BROWN & SHARPE THICKNESS GAGE

A thickness gage having six blades 0.0015, 0.002, 0.003, 0.004, 0.006, and 0.015 inch in thickness, respectively, which may be used individually or together for measurements up to 0.0315 inch, has been added to the line of mechanics' tools made by the Brown & Sharpe Mfg. Co., Providence, R. I. It is shown in the accompanying illustration. The blades are

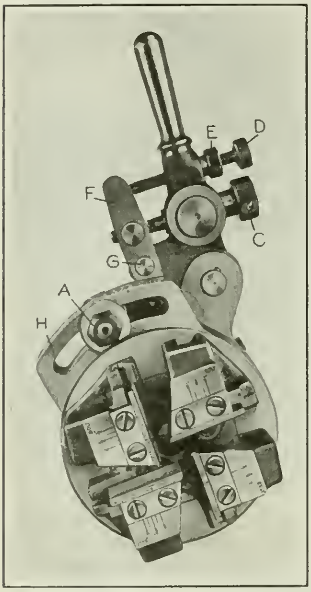


Brown & Sharpe No. 646 Thickness Gage

accurately ground to the specified thickness. The protecting blade has an eyelet that provides for hanging the gage on a carrying ring or on a hook. This gage will be found of value by automobile mechanics and owners for setting valve tappets, distributor points and spark plug gaps, fitting pistons, and making shims for eliminating rattle.

LANDIS STATIONARY DIE-HEAD

A stationary die-head equipped with a micrometer attachment which is particularly valuable when cutting threads of special form requiring one or more roughing cuts and a finishing cut, is a recent product of the Landis Machine Co., Inc., Waynesboro, Pa. It is possible to set this die-head so that the same amount of metal is left at all times for removal in the finishing cut. The head is graduated to suit both right- and left-hand threading of bolts and pipe. These graduations are placed on the closing ring above the circular slot. To adjust the die-head for cutting threads of a given size, the clamping nut *A* in the accompanying illustration is first loosened with the left hand, and then the closing ring is swiveled by the right hand to the proper graduation. Closer adjustment can then be made by means of the micrometer attachment. This is accomplished by first loosening lock-nut *E*, and then turning the micrometer screw *C*. This screw is turned in the counter-clockwise direction to increase the diameter to which the chasers are set, the turning of the screw causing the upper part of link *F* to swing toward the left about center *G*. This action pulls the closing ring *H* toward the right. If the micrometer screw *C* is turned in the clockwise direction, the movement of link *F* toward the right results in a decrease in the diameter of the chaser setting. After making the micrometer adjustment the stop-screw *D* should be set against the link *F* and locked in place by means of the lock-nut *E*.



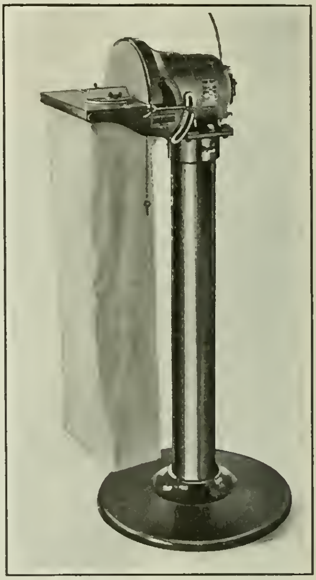
Landis Stationary Die-head with Micrometer Adjustment

To adjust the chasers for taking a roughing cut, the micrometer screw *C* is turned in the counter-clockwise direction until the desired setting has been obtained, the stop-screw *D* being left in its originally located position. A number of roughing cuts can then be made by adjusting the die-head after each cut, again turning screw *C* to effect this adjustment. After the roughing cuts have been completed, the micrometer screw should be revolved until link *F* comes against the stop-screw *D*. The die-head is then set for taking the finishing cut.

This die-head can be applied to turret and engine lathes, hand screw machines, and other types of threading machines in which the work revolves and the threading head remains stationary. For application to a turret lathe, the die-head is equipped with a shank that fits the sockets of the turret. Application to the cross-slide of the engine lathe is made by means of a special knee bracket having a boss machined to fit a counterbored hole in the back of the die-head. It is necessary to provide a special dead center that will fit bores in both the bracket and the die-head. Work may also be gripped in a chuck and threaded without the use of centers when the shape of the part necessitates this form of support.

SYRACUSE PORTABLE MOTOR-DRIVEN DISK SANDER

A 9-inch motor-driven disk sander mounted on a pedestal as illustrated in order to provide an equipment readily portable about the shop has been brought out by the Syracuse Sander Mfg. Co., Inc., 1232-1234 S. State St., Syracuse, N. Y. The sander is driven by a 1/6-horsepower enclosed motor having an attached switch. Current may be received from a lamp socket. The sander can be swiveled on top of the pedestal so as to bring the disk toward the light. The table tilts 45 degrees below horizontal and 15 degrees above it, a graduated plate indicating the angularity of a setting. The table is secured in a set position by tightening a thumb-screw. An angle gage graduated in degrees is furnished. The disk is covered with emery cloth on one side for sanding metal parts and with garnet paper on the opposite side for wood work. Dust from the work is sucked into the canvas bag attached to the under side of the table. The operator is thus relieved of all the annoyance occasioned by flying dust. This sander is also supplied without a pedestal for mounting on benches.



Syracuse 9-inch Disk Sander

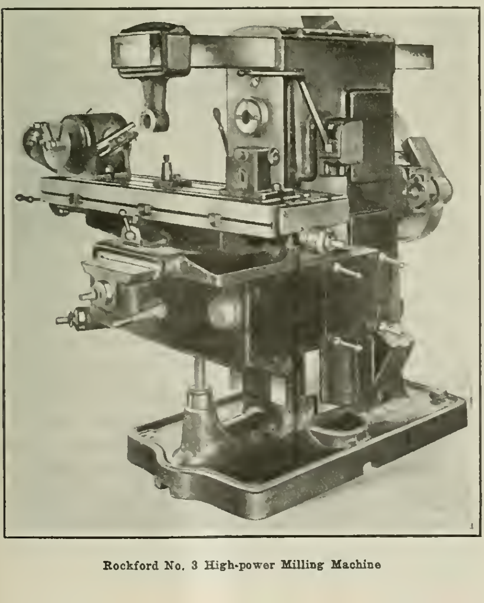
ROCKFORD NO. 3 HIGH-POWER MILLING MACHINE

The Rockford Milling Machine Co., Rockford, Ill., has brought out a No. 3 high-power milling machine of the single-pulley type which differs in certain respects from the No. 3 machine previously described in the technical press. The use of driving shafts is entirely eliminated for conveying power to the knee. The transmission is all enclosed in the knee casting which projects on the right-hand side of the column and has an unusually wide bearing surface. A long gear is located in a vertical position in that part of the transmission housing which extends over the bearing face just referred to. Throughout the range of the movement of the knee, the long gear is always in mesh with the feed reverse and quick-return gears, which are located inside of the column directly behind the plane of the bearing face. This long gear also connects through a pair of bevel gears with a second long gear, located horizontally at the side of the knee and meshing with the gears operating the knee, saddle and table. It will be seen, therefore, that the entire feed drive is through gears which are always in mesh, and that there are no connecting shafts.

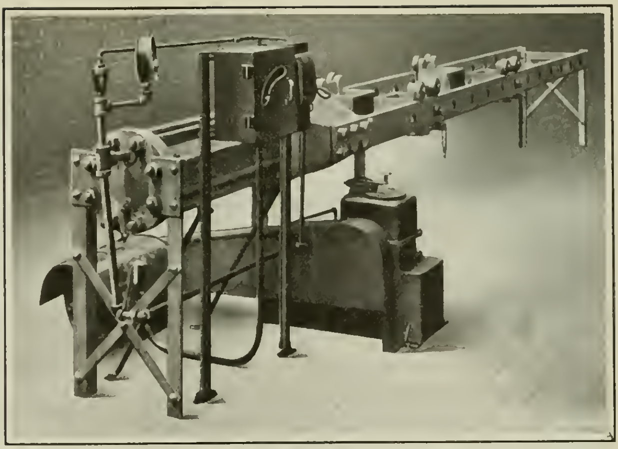
A feed-controlling lever, which determines whether the transverse or vertical feed is engaged, is located on the left-hand side of the knee within easy reach of the operator. This lever is provided with a dial on which are plainly marked the transverse and vertical positions of engagement as well as the neutral position, in which neither feed is engaged. The vertical and transverse feeds can also be controlled by a lever on the left-hand side of the knee near the column and within convenient reach of the operator when standing back of the table for such operations as boring. The shaft connecting this lever with the feed-control box extends through the back flange of the knee and projects to a point where it reaches the dogs of the automatic stop mechanism. On the side of the column there is a long vertical boss on which dogs may be adjusted to contact with the feed-bar and disengage the vertical feed at any predetermined point. This boss also has permanent safety stops for disengaging the feed within safety limits.

This machine, like the former design, has the rectangular over-arm and a column of the conventional box form enclosing practically the entire working mechanism. The splash system of lubrication is employed, each individual unit comprising an oil chamber where all gears run constantly in an oil bath. Either belt or motor drive can be supplied, a single constant-speed pulley mounted on Hyatt roller bearings being used for belt-driven machines. When a motor is used, it is mounted on a heavy pedestal bolted to the rear of the column and base, and it drives through a high-speed silent link chain provided with safety guards.

The machine table has automatic longitudinal and cross-feeds of 34 and 12 inches respectively, and there is an automatic vertical feed of 20 inches. Sixteen speed changes are provided ranging from 12 to 350 R. P. M. and 12 feed changes ranging from ½ inch to 16 inches per minute.



Rockford No. 3 High-power Milling Machine



Oilgear 25-ton Horizontal Press on which the Speed of Ram Travel may be changed instantly

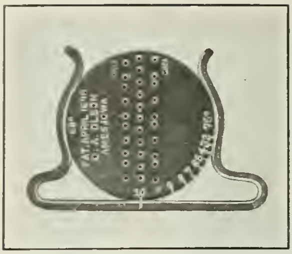
OILGEAR HORIZONTAL PRESS

A horizontal hydraulic press equipped with an "oilgear" control by means of which a wide range of ram speeds is made possible, has just been brought out by the Oilgear Co., 60-64 Twenty-seventh St., Milwaukee, Wis. The machine has a capacity of twenty-five tons at pressing speeds of from ¼ to 6 inches per minute. The maximum speed of the ram while traveling to the work is 37 inches per minute, and the maximum return speed, 56 inches per minute. The speed of ram traverse may be changed instantly by operating a small control lever conveniently located on top of the pump housing at the front of the machine. It is said that the ram stroke begins without shock and is made without pulsation. Suitable overload relief valves permit the ram to be driven at full speed against a stop without danger of injuries resulting to the machine parts or the work.

The pump is driven by a constant-speed two-horsepower motor located at the rear of the head end of the machine, as illustrated. The stops are of a V-shape and can be located along the machine frame as desired, being held in place by steel pins. The center of the ram is located 32 inches above the floor, and the distance between stop supports is 24 inches. The maximum stroke of the ram is 30 inches. At full capacity, a pressure of 800 pounds per square inch is exerted on the piston head, the cylinder being 9 inches in diameter. All working parts are lubricated automatically and no adjustments are necessary to keep the press in operating condition. This machine has been used for such work as assembling wheels on axles of saw-mill carriages and heads into pipe rollers. It is adaptable to many other jobs.

"AMES" LETTERING INSTRUMENT

For reducing the time consumed in placing guide lines on drawings when lettering titles and notes, the O. A. Olson Mfg. Co., 706 Wilson Ave., Ames, Iowa, has placed on the market the instrument shown in the illustration. This device consists of a nickel-plated tempered steel frame which retains a transparent celluloid disk that may be swiveled in the frame. The disk has three parallel rows of taper holes which furnish a means for quickly drawing guide lines without the necessity of first locating them by means of a scale. In laying out the guide lines, the instrument is placed with the base in contact with a T-square or straight edge, and then pulled alternately to the right and to the left by means of a pencil placed in the holes of the disk, the pencil being, of course, shifted from one hole to the next after each movement to and fro. The vertical height between the



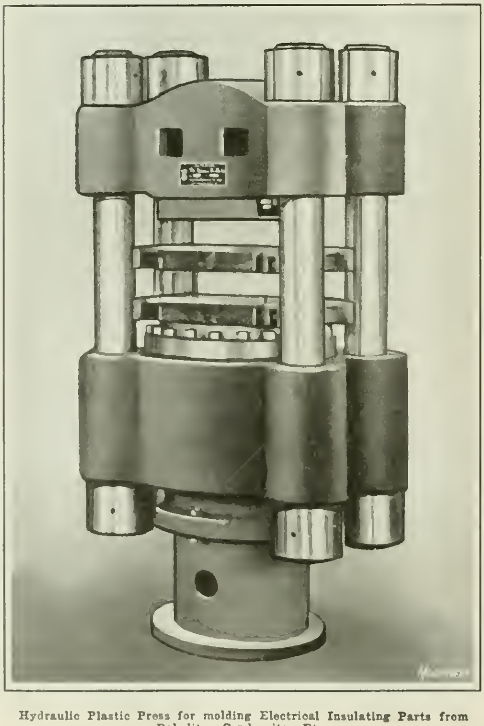
"Ames" Lettering Instrument

guide lines may be regulated by swiveling the disk in the frame. As the middle row is equally spaced, cross-section lines can be drawn uniformly. Slanting lines for letters may be quickly drawn after placing the instrument with an open and a closed end in contact with the straightedge.

HYDRAULIC PLASTIC MOLDING PRESSES

A line of hot- and cold-plate presses designed for producing small electrical insulating parts from bakelite, condensite and other non-conducting compositions, is now being built by the Hydraulic Press Mfg. Co., 84-88 Lincoln Ave., Mount Gilead, Ohio. Many of the parts which the presses are capable of producing are used in the construction of radio apparatus. There are three styles of presses: A double-opening, square-platen press which is intended for removable dies, and on which the upper plates are used for heating the material being molded, and the lower ones for cooling it; a single-opening square-platen press also intended for use with removable dies and in batteries of three, two machines of which are provided with hot plates, and the third with cold plates; and a single-opening rectangular-platen press for fixed dies, which is arranged for alternately heating and chilling the same plates.

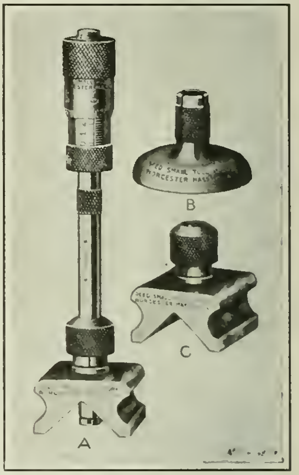
In the molding operation, the material is first heated to make it plastic and then pressure is applied to cause the material to conform to the die. For this part of the process, the hot plates are heated either by the circulation of steam, by gas flames, or by electrical resistance units. In the second part of the operation, the material is cooled while still in the die and under pressure. This is accomplished by chilling the plates by the circulation of water. Some materials may not require the procedure outlined. The pressure is applied in the upward direction. Each machine is equipped with four strain rods.



Hydraulic Plastic Press for molding Electrical Insulating Parts from Bakelite, Condensite, Etc.

REED INSIDE MICROMETER WITH HEIGHT-GAGE ATTACHMENT

An inside micrometer which may be furnished with base attachments for converting it into a height gage or instrument for detecting misalignment between surfaces has recently been placed on the market by the Reed Small Tool Works, Cherry and Vine Sts., Worcester, Mass. The micrometer is regularly supplied with five rods and a spacer that enable the taking of measurements from 2 to 7 inches, but additional spacers may be furnished for taking measurements up to 32 inches. The minimum setting of the micrometer permits the measuring of the smallest-sized automobile cylinders. The spindle has a ½-inch movement. The measuring rods are fitted with hardened tool steel anvils which are adjustable for wear, the rods being interchangeable on the threaded stud at one end of the micrometer head. The rods may be used singly or in combinations. A detachable handle adapts the micrometer to use with both right- or left-hand work.



Reed Micrometer with Height-gage Bases

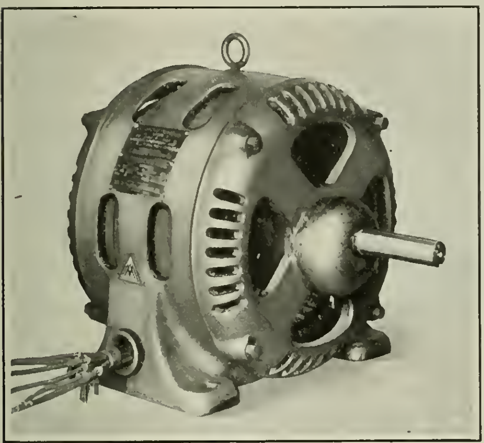
The micrometer can be quickly transformed into a height gage or misalignment detecting instrument by using the attachment shown at *C* and a rod. The micrometer is shown mounted on the attachment at *A*. The rod is inserted downward through the attachment until the anvil rests on the surface from which the measurement is to be taken, after which the quick-clamping knurled nut on the attachment is tightened by means of the fingers to hold the measuring rod firmly in position. When so arranged, the instrument is particularly useful in obtaining the height of projections and the locations of bushings in jigs, in measuring from the bottom of a groove to other surfaces in planer work, and in setting planer tools. The V-groove in the bottom of the base adapts the instrument to use with cylindrical parts as in measuring the distance between shafts for detecting misalignment. By inserting a drill rod in the base and attaching a standard indicator to this drill rod, a surface gage will be obtained that will be found useful in straightening shafts or in checking variations in the distance between surfaces. A scriber can be clamped to the rod.

The round base attachment shown at *B* is intended mainly for adapting the micrometer to ordinary height-gage applications. The upper end of the base is split vertically and may be adjusted to produce a friction on the measuring rod. This adjustment provides for eliminating side play should any wear take place on the parts from constant use. It also holds the base and the measuring rod together as the instrument is lifted from one surface to another.

WATSON MULTI-SPEED ALTERNATING-CURRENT MOTOR

A line of multi-speed alternating-current motors which afford speeds of 600, 720, 900, and 1200 revolutions per minute are now being introduced on the market under the trade name of "Watson," by the Mechanical Appliance Co., Milwaukee, Wis. Until recently the standard 4-speed windings for alternating-current motors gave 600, 900, 1200 and 1800 revolutions per minute on 60-cycle circuits, the two higher speeds being twice the two lower speeds. On this line of motors the narrower speed gap has been obtained by using an independent winding on the stator for each speed. In this manner speeds approaching those of direct-current motors are made possible.

The motor is of the squirrel-cage type and is said to carry a full rated load indefinitely without a temperature rise exceeding 40 degrees Centigrade, or a 25 per cent overload



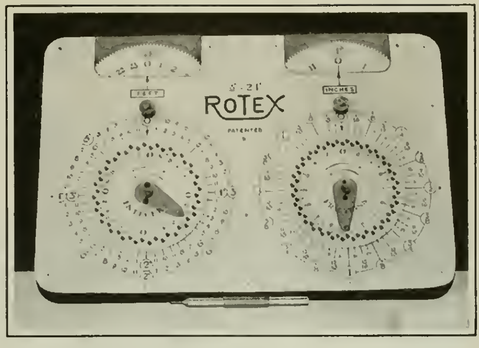
Watson Multi-speed Alternating-current Motor which may be run 600, 720, 900 and 1200 Revolutions per Minute

for two hours without a temperature rise of more than 55 degrees Centigrade. The motor is furnished for constant horsepower, constant torque, or any combination of both in two, three, or four speeds, for 60-cycle circuits. This motor may be supplied for both automatic and remote control. The speed range adapts the motor for driving some machine tools which previously could only be driven by direct-current motors.

LEINERT RAPID CALCULATOR

A rapid calculator for adding and subtracting feet and inches has been placed on the market by W. Leinert, 410 W. 23rd St., New York City, under the trade name of "Rotex." It will be seen from the illustration that the device has two circular scales, one of which is divided into forty-eight equal parts, and the other into sixty-four. The former is used in adding or subtracting integers of feet and inches, and the latter in dealing with fractions of an inch. The graduations of the scales are marked with black figures in clockwise sequence for use in adding, and with red figures in counter-clockwise sequence for use in subtracting.

Within each scale is a circular rotative disk that is graduated at its periphery to correspond with the graduations of the scale. Each disk is mounted on a pinion which engages a gear that may be seen in the slots near the top of the device, there being a provision for readily disengaging the gear and pinion. The disks have perforations that furnish a means for rotating them with a stylus supplied for the



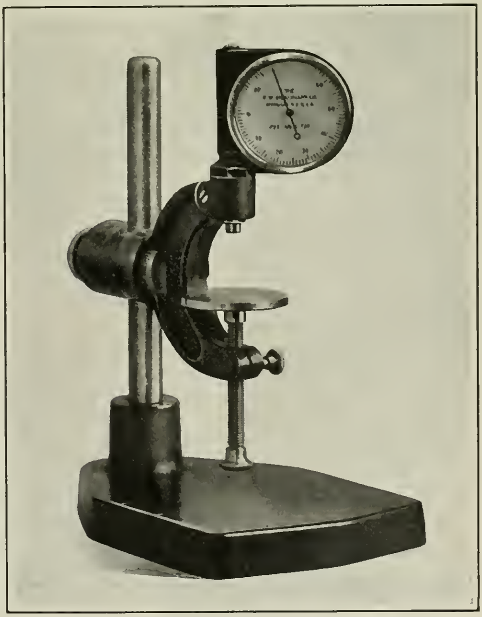
"Rotex" Calculator for adding and subtracting Feet and Inches

purpose. A rotative celluloid pointer mounted co-axially with each disk serves to indicate the last item of a calculation, in case of an interruption.

In using this calculator for adding sums, the disks are turned from the zero mark in a clockwise direction to proper divisions on the fixed scale having black figures. In subtracting, the disks are turned counter-clockwise to the proper divisions having red figures. The result in feet and inches is read at the zero marks. At each complete rotation of the right-hand gear a buzzer signals to indicate that a total of 12 inches should be transferred to the integer scale.

HORSTMANN INDICATING CALIPER

An indicating caliper having a head which may be swiveled about a complete circle and remains fixed in any desired position without the use of clamps, is now being manufactured by F. W. Horstmann Co., 196-210 Coit St., Irvington, N. J. The caliper may be supplied mounted on a stand as illustrated, or without this accessory. Except for the swivel head, the instrument is of the same design as the standard caliper made by the company. The dial graduations read



Horstmann Indicating Caliper with a Swiveling Head to thousandths of an inch. The caliper is made in six sizes from 1 to 6 inches and each size has a range of 1 inch. It may be clamped on the post of the stand either in a straight or tilted position. Although the stand is sufficiently heavy for supporting ordinary work, holes may be drilled in the base for fastening to a bench to prevent it from tipping over. When used with a stand the caliper may be supplied with a larger anvil than is furnished on the instrument when it is intended for hand use. The caliper illustrated is equipped with the larger anvil.

NEW MACHINERY AND TOOLS NOTES

Lathe Sub-head: Hendey Machine Co., Torrington, Conn. An attachment for the standard lathes of this company's manufacture known as a "sub-head," designed to facilitate the cutting of worms, threads, hobs, etc., having unusually long leads. The attachment fits the inner vees of the lathe and is driven by special gearing attached to the spindle nose which gives a six to one reduction in speed relative to the lathe spindle. The faceplate turns on a hollow spindle, thus permitting the use of a dead center. The attachment is made for all Hendey lathes from 12 to 24 inches inclusive.

Magnetic Chucks: O. S. Walker & Co., Inc., Worcester, Mass. A line of magnetic chucks of the rectangular type for horizontal use, designed primarily for grinding machines made by the Diamond Machine Co., Providence, R. I., and the Norton Co., Worcester, Mass., but equally well adapted for other makes of similar capacity, as well as for planers and milling machines. The chucks are plain in style and have working surfaces ranging from 13¾ by 24 inches to 15 by 71½ inches. The range in weight is from 290 to 1150 pounds.

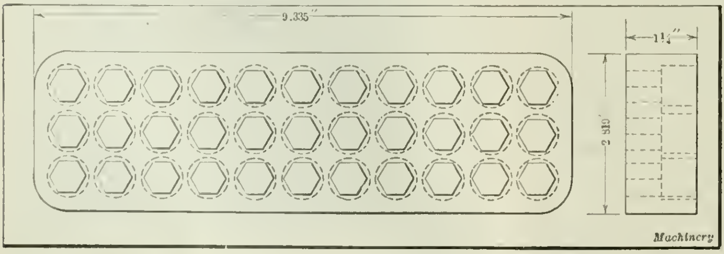
DRILLING HEXAGONAL HOLES IN A MOLD FOR BAKELITE PARTS

The cost of making a mold for producing small bakelite insulators in quantities of thirty-three at a time was greatly reduced through the use of hexagonal drills manufactured by the Watts Bros. Tool Works, in machining the holes in which the insulators are molded. These insulators measure 0.580 inch across flats and ⅜ inch in thickness. They are used in large quantities by the electrical industry. From the illustration it will be seen that the holes are arranged in parallel rows. The center to center distance between any adjacent holes of a row is 0.8145 inch, and the depth of the hexagonal portion of each hole, ⅝ inch. The tolerance on the dimension across the flats of a hole was 0.001 inch. The mold was machined from Ketos tool steel, and hardened and ground to fit a steam jacket. It has been estimated that twenty-eight days would be required to make this mold if the hexagonal holes were produced by drifting and filing after round holes had been drilled. This method would ordinarily have been applied to this work, because the mold had to be made in one piece. However, by drilling the hexagonal holes by means of the hexagonal drills and a jig plate, the mold was made in three days.



Construction of Mold for producing Bakelite Insulators, the Hexagonal Holes of which were machined by employing Hexagonal Drills

NEW BOOK ON INTERCHANGEABLE MANUFACTURING

Principles of Interchangeable Manufacturing. By Earle Buckingham. 254 pages, 6 by 9 inches; 211 illustrations. Published by The Industrial Press, 140-148 Lafayette St., New York City. Price, $3.

The purpose of this book is to present a complete and comprehensive treatise dealing with the subject of interchangeable manufacturing as a whole. Such a book has not heretofore been available to those interested in interchangeable manufacturing in the machine building and metal working fields, although many articles dealing with various phases of interchangeable manufacturing have appeared from time to time in the technical press.

The development of interchangeable manufacturing is closely interwoven with many distinctly American manufacturing methods and processes and every large American industry has contributed its share to the progress made along this line. Different plants working independently have often achieved the same results by widely different methods. The author has attempted to define and emphasize the underlying basic principles, using specific examples only when necessary to illustrate the application of these principles in actual manufacturing processes. The information upon which this treatise is based has been gathered from many manufacturing plants, both large and small, in this country and in Canada; but the author mentions especially the Pratt & Whitney Co., Hartford, Conn., with whose cooperation this treatise has been written. The author has seen every method discussed in successful operation, some in one plant, and some in another. For more than ten years he has been in constant touch with many of the detailed manufacturing problems that arise in the production of interchanegable mechanisms in large quantities. During the war his activities in many manufacturing plants in connection with ordnance work made it apparent to him that the absence of common methods of interpretation of drawings, tolerances, and specifications, the lack of uniform gaging methods and misunderstanding of many of the factors of interchangeable manufacturing, presented an urgent need for a complete treatise on this subject.

In the arrangement of the material available on the subject of interchangeable manufacturing, the general principles involved in the industrial application of this method of production have been taken up first, and a separate chapter has then been devoted to the definition of the terms used, so that there will be no misunderstanding as to the meaning of the terms occurring later in the book. The influence of interchangeable manufacturing processes on machine design and the purposes of models are then dealt with, followed by a complete and minute discussion on the dimensioning of drawings intended for use in interchangeable manufacturing. This is followed by a discussion of the principal elements that govern mechanical production, the equipment required for interchangeable manufacturing (including machines, jigs and fixtures); the gaging equipment necessary; and the principles of inspection and testing.

Special chapters are also devoted to the subjects of manufacture for selective assembly, and methods used in small quantity production on an interchangeable basis. An entire chapter deals with the service factor in interchangeable manufacturing, because no manufactured machine is purchased for itself alone, but for the service it is supposed to render.

PERSONALS

R. D. Shields has been appointed assistant general manager of the Ohio Machine Tool Co., Kenton, Ohio. Mr. Shields has been chief engineer of this company for several years and will continue in that capacity.

Edward R. Abbott, formerly New York representative for the Taft-Peirce Mfg. Co., is now with the DuPont Engineering Co., Wilmington, Del., as sales representative for their Wilmington shops recently opened to contract work.

L. C. Bullington, who has been assistant to the manager of the Power Department of the Westinghouse Electric & Mfg. Co., has been made assistant manager and will have charge of the general work of the Power Department.

J. G. Benedict, general manager of the Landis Machine Co., Waynesboro, Pa., sailed July 8 for a combined business and pleasure trip abroad. Mr. Benedict will be gone for about two months and his itinerary will include England, France, Holland, Belgium, and Germany.

Charles H. Bluske has been appointed district sales manager of the Los Angeles office of the Economy Fuse & Mfg. Co., Chicago, Ill. The Los Angeles office is at 1304 Maltman Ave. Mr. Bluske was formerly connected with the Pacific States Electric Co. of Los Angeles.

P. J. Connor, formerly traveling representative for the International Machine Tool Co., Indianapolis, Ind., manufacturer of the Libby turret lathe, and recently connected with the Essley Machinery Co., Chicago, Ill., is now engaged, in an engineering capacity, with the Haynes Stellite Co. with headquarters in New York.

S. Glen Vinson, secretary and general manager of the Ideal Electric & Mfg. Co., Mansfield, Ohio, sailed recently for the Orient where he will make a survey of business conditions. Mr. Vinson will visit all the larger cities in Japan, China, Philippine Islands, and India. He expects to return to the United States about October.

R. S. Gildart of Cleveland, Ohio, has become advertising manager of the General Fireproofing Co., Youngstown, Ohio. Mr. Gildart was formerly director of publicity for the American Malleable Castings Association, Cleveland, prior to which he was advertising manager for the P. B. Yates Machine Co., Beloit, Wis., and the Kelvinator Corporation, Detroit, Mich. The General Fireproofing Co. is engaged in the manufacture of steel office furniture, filing equipment, concrete reinforcements, etc.

C. F. Ford, for several years with the Chicago Pulley & Shafting Co. has recently become connected with the engineering sales force of the W. A. Jones Foundry & Machine Co., Chicago, Ill., manufacturer of speed reducers and power transmission machinery. Mr. Ford will be located in the near future in Minneapolis as manager of the company's branch there. Some years ago Mr. Ford was transmission engineer for the W. A. Jones Foundry & Machine Co., and acted in that capacity over an extended period.

W. H. White has been appointed New York representative of the Mahr Mfg. Co., Minneapolis, Minn. He will have offices at 56 Murray St., New York City. The Mahr Mfg. Co. manufactures the "Mahrvel" line of oil-burning equipment, rivet forges, torches, and furnaces. Mr. White until recently was associated with the Mushet Steel and Taylor Iron interests in the United States and Canada. His experience in the iron and steel business during the last ten years will be useful to him in dealing with heat-treating problems.

* * *

OBITUARY

W. H. Holland, president and general manager of the Sibley Machine Co., 8 Tutt St., South Bend, Ind., who died Wednesday, June 14, was prominently identified with many manufacturing companies in South Bend and northern Indiana, and had also several other business interests, serving as vice-president of the Citizens' National Bank of South Bend. He was also president of the Motor Casting Co., president of the Elkhart Iron Works, president of the Clover Leaf Mfg. Co., vice-president of the South Bend Bait Co., and a director of the American Earth Works. Mr. Holland was born in Florena, Neb., June 4, 1866. He came to South Bend with his parents when five years old, and at the age of fourteen he started to work at the Sibley & Ware Mfg. Co. Mr. Holland is survived by his wife and his daughter, Mrs. Bernard Voll of Cambridge, Mass.

TRADE NOTES

Albro-Clem Elevator Co., 500 Erie Ave., East, Philadelphia, Pa., announces that it has moved its district sales and service office in New York City to 165 Broadway.

Economy Fuse & Mfg. Co., Chicago, Ill., announces that the Pittsburg sales office of the company has been moved from 2223 Farmers Bank Bldg., to 1006 Peoples Bank Bldg., at Fourth Ave. and Wood St.

Marvin & Casler Co., Canastota, N. Y., manufacturer of Casler boring heads and chucks announces that it has taken over the manufacture and selling of the castellating and hexing machine designed by the Manufacturers' Consulting Engineers of Syracuse, N. Y.

S. & S. Machine Works, 4522 Lexington St., Chicago, Ill., has been formed by E. V. Swangren, formerly vice-president and superintendent of the F. J. Littell Machine Co., and W. N. Stevenson, formerly secretary and chief engineer of the same company. The partnership has been formed for the purpose of engaging in engineering and machine shop work.

Bastian-Blessing Co., W. Austin Ave. at La Salle St., Chicago, Ill., manufacturer of Rego welding and cutting apparatus has taken over the entire output of the St. Paul Welding & Mfg. Co.'s line of soldering equipment, trucks, preheaters and acetylene generators. The St. Paul Welding & Mfg. Co. will be the service distributors of Rego welding and cutting equipment and supplies at St. Paul, Minn.

Haberkorn & Wood is the name of a partnership formed by A. C. Haberkorn, formerly Detroit branch manager of Manning, Maxwell & Moore, Inc., and the Biggs-Watterson Co., and E. E. Wood, formerly sales manager of the Jones & Lamson Machine Co. An office and warehouse have been opened at 620 E. Hancock Ave., Detroit, Mich. The firm will handle a line of machine tools, cutting oils and compounds, as well as permanent mold aluminum alloy castings.

COMING EVENTS

August 28-September 2—Annual Safety Congress of the National Safety Council in Detroit, Mich. Secretary S. J. Williams, 168 N. Michigan Ave., Chicago, Ill.

September 4-9—Annual meeting of the American Chemical Society at Pittsburg, Pa. Further information may be obtained from R. S. Clark, office of the secretary, Carnegie Institute of Technology, Pittsburg, Pa.

September 11-15—Sixteenth annual convention and fourth annual exhibition of the Association of Iron and Steel Electrical Engineers at Cleveland Public Hall, Cleveland, Ohio. John F. Kelly, secretary, Empire Building, Pittsburg, Pa.

September 11-16—Eighth national exposition of chemical industries in the Grand Central Palace, New York City. Managers, Charles F Roth and Fred W Payne, Grand Central Palace, 46th St and Lexington Ave., New York City.

October 2-7—Annual convention and exposition of the American Society for Steel Treating in Detroit, Mich., General Motors Bldg. Secretary, W H Eiseaman, 4600 Prospect Ave., Cleveland, Ohio.

October 26-27—Automotive production meeting of the Society of Automotive Engineers to be held in Detroit. Further information may be obtained from the Society of Automotive Engineers, 29 W. 39th St., New York.

December 4-7—Annual convention of the American Society of Mechanical Engineers, in the Engineering Societies Bldg., 29 W. 39th St., New York City. Calvin W. Rice, secretary.

December 7-13—National Exposition of Power and Mechanical Engineering at the Grand Central Palace, New York City. Charles F. Roth, manager, Grand Central Palace, 46th St., and Lexington Ave., New York.

SOCIETIES, SCHOOLS AND COLLEGES

New York University, New York City, announces two series of lectures which will be given at the University, one on the Geology of Commerce and Industry, and one on the Commercial Geology of the Metals. Further information may be had by writing the secretary of the School of Commerce, New York University, Washington Square, or to Dr. Ernest R. Lilley, New York University, University Heights, New York City.

Pennsylvania State College, State College, Pa. Bulletin describing a course in Industrial Organization and Administration, which will be held at the State College from August 28 to September 9, under the direction of Professor Edward J. Kunze, assisted by Professors J. O. Keller and P. P. Henshall of the Department of Industrial Engineering. Complete information may be obtained by addressing Professor Edward J. Kunze, State College, Pa.

NEW BOOKS AND PAMPHLETS

Trade Standards in the Pump Industry. 21 pages, 6 by 9 inches. Published by the Hydraulic Society, 50 Church St., New York City.

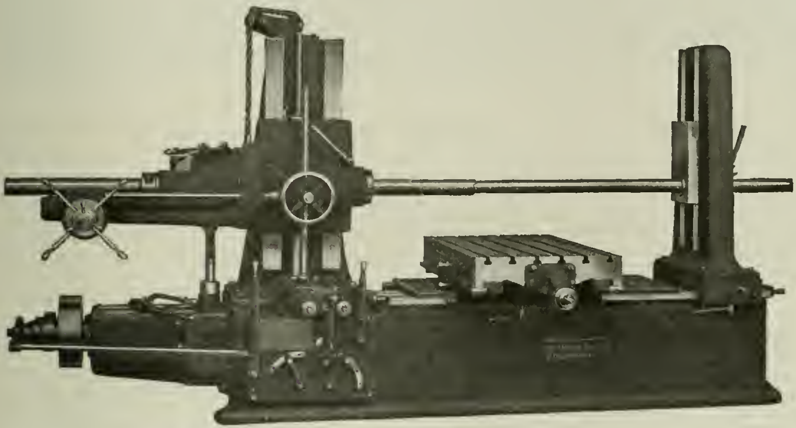
Interference Methods for Standardizing and Testing Precision Gage-blocks. By C. G. Peters and H. S. Boyd. Scientific Paper No. 436 of the Bureau of Standards, Washington, D. C. 36 pages, 7 by 10 inches. Published by the Superintendent of Documents, Government Printing Office, Washington, D. C. Price, 10 cents.

Metallographic Etching Reagents. By Henry S. Rawdon and Marjorie G. Lorentz. Scientific Paper No. 435 of the Bureau of Standards, Washington, D. C. 41 pages, 7 by 10 inches. Published by the Superintendent of Documents, Government Printing Office, Washington, D. C. Price, 15 cents.

Distance lends enchantment to—lots of things but NOT to the

"PRECISION"

Boring, Drilling and MILLING MACHINE



The closer you get, and the more you know it, the better you like it; it has no tricks to plague you either before or after you get familiar with it, which does not take long, because

LUCAS MACHINE TOOL CO. NOW AND ALWAYS OF **CLEVELAND, OHIO, U.S.A.**

FOREIGN AGENTS: Alfred Herbert, Ltd., Coventry. Societe Anoyme Belge, Alfred Herbert, Brussels. Aux Forges de Vulcain, Paris. Allied Machinery Company, Turin, Barcelona, Zurich. Benson Brothers, Sydney, Melbourne. V. Lowener, Copenhagen, Christiania, Stockholm. R. S. Stokvis & Zonen, Rotterdam. Andrews & George Company, Tokyo, Japan.

How to Make Commercial Type Radio Apparatus. By M. B. Sleeper. 159 pages, 5¼ by 7¾ inches. Published by the Norman W. Henley Publishing Co., 2 W. 45th St., New York City. Price, 75 cents.

A man who builds and designs his own radio equipment often wishes to compare it with the equipment of commercial design, and it is for this purpose that this guide book has been issued, which gives information in compact form on commercial type radio apparatus. The book describes in detail many commercial types of transmitting spark and vacuum tube sets, both telephone and telegraph, and receiving equipment of all kinds. There are ninety-eight illustrations, which make it easy for the experimenter to follow the descriptions.

Notes on Mechanical Drawing. By Rolland S. Wallis. 64 pages, 6 by 9 inches; 87 illustrations. Published by the Engineering Extension Department, Iowa State College, Ames, Iowa. Price, 50 cents.

This is a supplement to the drawing courses conducted by the Engineering Extension Department of the Iowa State College. It gives a general survey of the principles of mechanical drawing, reviewing the instruments required and their use, and devoting considerable space to freehand lettering as well as lettering produced by drawing instruments. It then briefly reviews the standard methods of projection, dimensioning, and the drawing of simple machine details. It closes with a useful chapter on drafting-room geometry.

Industrial Unionism in America. By Marion Dutton Savage. 344 pages, 7½ by 5 inches. Published by the Ronald Press Co., 20 Vesey St., New York City. Price, $2.25.

In this book, as stated in the preface, an attempt has been made to describe unionism, with its many variations, and to consider the direction in which organized labor seems to be moving. The author has assumed on the part of the reader some knowledge of the many reasons for the existence of the labor movement. No attempt has been made to justify or condemn the fact of organization among the workers. The subject matter is divided into three main heads as follows: Industrial Unionism within the American Federation of Labor; Revolutionary Industrial Unionism including Workers of All Industries; and Independent Industrial Unionism.

Iron and Steel. Pamphlet published by the Bureau of Education of the United States Department of the Interior, Washington, D. C. Sent free on application.

This pamphlet contains an outline of a reading course on the manufacture of iron and steel, including information on blast furnaces and treatises on the metallurgy of steel. The pamphlet is prepared by the American Library Association for the Bureau of Education of the United States Department of the Interior. It lists fourteen books, which form a course covering the whole iron and steel industry. Among the books included are "Iron and Steel," published by The Industrial Press, 148 Lafayette Street, New York City, which contains a complete outline of the entire subject of the manufacture of iron and steel of different kinds—wrought iron, open-hearth steel, bessemer steel, tool steel, high-speed steel, electric steel, steel castings, gray iron castings, malleable iron, etc.

Handbook of the Electric Power Club. 284 pages, 4 by 7 inches. Published by the Electric Power Club, 1017 Olive St., St. Louis, Mo.

This is the fourteenth edition of the handbook of the Electric Power Club, an association of manufacturers of electric power apparatus and control equipment, organized for the standardization, improved production, and increased distribution of electrical machinery and apparatus. The handbook covers substantially all of the standardization thus far accomplished by the Electric Power Club and its predecessor, the American Association of Electric Motor Manufacturers, which was organized in 1908. The handbook contains a mass of valuable information for those who use electric power apparatus. For example, it contains information relating to pulley sizes, belt speeds, methods of gearing motors, etc. It should be of especial value in connection with the providing of motor drives for machine tools and industrial machinery in general.

Steam Turbines. By William J. Goudie. 804 pages, 8½ by 5½ inches. Published by Longmans, Green & Co., 55 Fifth Ave., New York City. Price, $10.

This is the second edition of Professor Goudie's book on steam turbines. As it was considered that a mere revision would not bring the book thoroughly up to date, it has been almost entirely rewritten. While the general scheme of the first edition has been followed, the addition of new material has increased the number of chapters from sixteen to eighteen. The thermodynamic portion is based on Callendar's characteristic equations for steam and four diagrams giving the properties of superheated and supersaturated steam are included. A new chapter has been added on mechanical reduction gears, with special reference to marine turbines. The section on critical speeds of rotors has been extended to include the multiple bearing case. Improved methods of dealing with the condition curve, reheat factor, internal efficiency, and also new methods of provisional design have been developed. The book is intended for the use of engineers engaged in the design or operation of steam turbines, as well as for engineering students.

Radio Experimenter's Handbook. By M. B. Sleeper. 143 pages, 6 by 4 inches. Published by the Norman W. Henley Publishing Co., 2 W. 45th St., New York City. Price, $1.

The purpose of this book is to answer the practical problems that confront those who are beginning to experiment in the radio field. All deeply theoretical and mathematical discussions have been omitted, and the apparatus considered is limited to simple and practical instruments capable of receiving signals from broadcasting stations as well as from radio telegraph stations. The material is divided into sixteen chapters as follows: What is the Use of Having a Radio Station?; What Makes the Wireless Work?; Apparatus Used in Simple Damped Wave Transmitting Sets; Setting up and Operating a Damped Wave Transmitter; Apparatus Used in Simple Damped Wave Receivers; Setting up and Operating a Simple Damped Wave Receiver; Radio Antennas and Grounds; Advanced Damped Wave Receiving Apparatus; How Does an Audion Work?; Damped Wave Audion Receiving Apparatus; Advanced Damped Wave Audion Receiving Apparatus; What is an Undamped Wave?; Undamped Wave Telegraph and Telephone Transmitters; Undamped Wave Receivers; the Audion Amplifier; Radio Rules and Regulations.

Production Engineering and Cost Keeping. By William R. Basset and Johnson Heywood. 311 pages, 6 by 9 inches; 117 illustrations. Published by the McGraw-Hill Book Co., 370 Seventh Ave., New York City. Price, $3.50.

The purpose of this book is not only to give practical assistance to production managers, foremen and cost accountants of machine shops, but also to furnish higher executives with a knowledge of the best in shop management practice. The principles and practice recommended have been developed in the course of years of actual installation of improved production, engineering, and cost keeping systems in metal trades plants. While no system, however successful in one shop, can be applied in its entirety in another shop, the underlying principles of management are essentially the same. A better idea of the contents will be obtained from the following chapter headings: What Production Planning Does; Purchasing as a Tool of Production; Need for Systematic Stock Keeping; Engineering the Product; Tool Issue; Laying out the Machines; the Central Control of Production; Controlling the Work in the Shop; Planning in the Jobbing Shop; the Fundamentals of Correct Time Study; Setting the Standard; Setting Piece Rates; Special Cases of Time Study and Rate Setting; Time Study on Automatic Machines; What a Cost System Can Do for You; the Fundamentals of Cost; Fixed Charges; Departmentalizing the Overhead Expense; Analyzing the Labor Costs; Accounting for Supplies; Getting the Overhead into the Finished Product; Handling Abnormal Expense; Gathering the Final Costs; the Statement of Condition and the Operating Statement; What Does it Cost to Sell?; Graphic Methods of Control.

NEW CATALOGUES AND CIRCULARS

New Departure Mfg. Co., Bristol, Conn. Folder entitled "New Departure Ball Bearings Win."

Monitor Controller Co., Baltimore, Md. Folder illustrating and describing the expansion unit of the Monitor thermaload starter.

Reading Chain & Block Corporation, Reading, Pa. Folder illustrating and describing the company's new "Everedy" electric hoist.

Ingersoll Milling Machine Co., Rockford, Ill. Bulletin entitled "The Ingersoll Adjustable Rail Milling Machine," illustrating and describing this machine and showing operations performed on it.

Hendey Machine Co., Torrington, Conn. Folder illustrating and describing the Hendey sub-head-stock, the primary purpose of which is to permit the chasing of screw threads having unusually long leads.

Jas. Clark, Jr., Electric Co., Louisville, Ky. Jasco Driller, a periodical published by the company, illustrating and describing its products and giving instructions for the care and maintenance of portable electric drills.

Newton Machine Tool Works, Inc., 23rd and Vine Sts., Philadelphia, Pa. Bulletin No. 57 illustrating and describing the company's radius-link grinding machine. The folder gives a table of general dimensions and specifications.

Schutte & Koerting Co., Philadelphia, Pa. Catalogue entitled "Koerting Fuel Oil Burning Systems," describing mechanical fuel oil-burning systems and fuel oil-burners in which the oil is atomized by low or high pressure air and steam.

W. C. Lipe, Syracuse, N. Y. Catalogue illustrating and describing in detail the Lipe automatic gear tooth chamfering machine, and showing some of the work done on it. Complete instructions for operating the machine are also included.

Brown Instrument Co., Philadelphia, Pa. Catalogue of resistance thermometers, explaining the theory of resistance thermometry, and illustrating and describing the various types of instruments made. The advantages and applications of each type are indicated.

Birdsboro Steel Foundry & Machine Co., Birdsboro, Berks County, Pa. Booklet illustrating and describing the Jackson belt lacer, showing clearly both the type of belt chains that results from the use of this belt lacer, and the method in which the belt lacer is applied.

Western Tool & Mfg. Co., Springfield, Ohio. Catalogue 19 of expanding mandrels, tool-holders, lathe dogs, C-clamps, shop furniture, emery wheel dressers, and vises. The catalogue is profusely illustrated, showing all the tools and devices manufactured, and giving complete lists of sizes and prices.

American Nickel Corporation, Clearfield, Pa. Bulletin No. 101 entitled "American Nickel—Its Properties and Uses." The bulletin gives a resume of the properties of the nickel products of the company and a list of purposes for which it is recommended, and contains a number of useful tables.

Acme Motor Truck Co., Cadillac, Mich. Catalogue for 1922, of Acme motor trucks, illustrating and describing seven models of the company's make. The catalogue is profusely illustrated, and gives complete description of the separate models; it also shows the construction of the prominent features of the Acme trucks.

Van Keuren Co., 362 Cambridge St., Boston, 34, Mass. Catalogue of modern measuring tools, illustrating, describing and giving prices of combination precision gage-blocks, gage-block accessories, plug gages, measuring wires for screw threads and profiling gages, lapped steel surface plates and light-wave measuring outfits.

Condensite Co. of America, Bloomfield, N. J. Catalogue entitled "Condensite in the Automotive Industry," illustrating and describing the various purposes for which condensite is used in automobile construction. Also catalogue treating of "Halowax Oil" in the rubber industry. This oil is used in the treatment of fabric to improve the bonding of rubber to it.

Kelly Lubricator Corporation, 107 N. Franklin St., Syracuse, N. Y. Folder illustrating and describing Auto-vac ball feed lubricators manufactured by the company for automatic, positive and economical lubrication. These lubricators are used on various types of machine tools and line-shafting. Loose-pulley lubricators are also illustrated and described.

General Welding & Equipment Co., 74 Brookline Ave., Boston, Mass. Catalogue entitled "Modern Welding and Cutting," illustrating and describing the "Gewe" automatic welding machines and automatic cutting machines. The automatic welding machine described is an entirely new design, having a self-feeding welding torch; numerous illustrations, showing the application of the apparatus, are included.

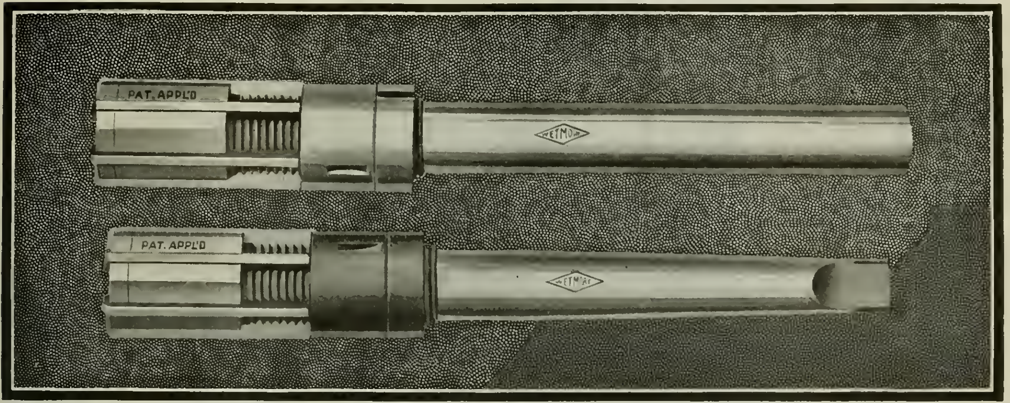
Philadelphia Gear Works, 1124 Vine St., Philadelphia, Pa. Catalogue for 1922 covering generated spur, bevel and spiral gears, rawhide and micarta pinions, worms and worm-gears, racks and lead-screws, speed-reducing units, sprockets and "Diamond" chains. In addition to the information about the company's product, the book contains a great deal of information on gearing, and a number of tables and formulas of use to gear designers and shop men.

Link-Belt Co., 910 S. Michigan Ave., Chicago, Ill. Catalogue entitled "Link-Belt Power Hoe," describing a new patented improved drag scraper, intended for use in storing and reclaiming materials. Bulletin describing the Link-Belt crawler crane, the newest machine that has been brought out by the Link-Belt shops in Chicago. This crane complete, without bucket, weighs twenty-two tons, and lifts safely ten tons at a 12-foot radius and three tons at a 30-foot radius.

Westinghouse Electric & Mfg. Co., East Pittsburg, Pa. Bulletin entitled "Arc Welding in Electric Railway Shops," known as Leaflet No. 1824. This publication describes the many advantages of arc welding, and gives figures showing the savings made possible by reclaiming worn out parts. The increased technical knowledge regarding the arc welding operation has extended the scope of the process, and the improvements in welding equipment, many of which are described in this bulletin, have greatly increased welding efficiency.

Colburn Machine Tool Co., Cleveland, Ohio. Bulletin B-103 entitled "Colburn Heavy-duty Boring and Turning Mills." This bulletin gives a very complete description of the new design of Colburn boring and turning mills together with halftone illustrations of the machines on which different parts are named for ready identification. A number of detail views of the most important mechanisms of the machines are also included, showing clearly the method of control and operation. A phantom view of the machine illustrates in a very good manner the lubricating system.

Metals Coating Co. of America, 495-497 North Third St., Philadelphia, Pa. Catalogue entitled "Schoop Metal Spraying Process," illustrating and describing the process and apparatus used for simultaneously melting and atomizing any of the commercial metals, impacting them on any surface so as to apply thereby a coating of any commercial metal on any surface according to the requirements. The catalogue completely illustrates and describes the process and the apparatus used in connection with it, and shows in addition the photographs of a number of applications in actual practice.



At Last! A Guaranteed Machine Reamer

—in Sizes *Under One Inch*

Last February we announced the perfection of Wetmore Expanding Machine Reamers—all sizes under one inch. Their reception by manufacturers was immediate. They filled a long-felt want. Since February, we have been kept busy supplying the demand for these small reamers of *guaranteed quality and accuracy.*

These new Wetmore Expanding Small Machine Reamers range in size by thirty-seconds from ⅝" to 31/32", inclusive—both straight and taper shank. In expanding these small reamers, there are no unnecessary screws to be loosened, because the expansion is taken care of by a cone nut and lock nut in rear of blades. The straight blades are held securely by a special method, exclusive to Wetmore Expanding Reamers.

These Wetmore "little fellows" typify the high standards of workmanship and materials that have made Wetmores *standard* in so many of America's largest plants. Here are some of the advantages of the general line of Wetmore Expanding Reamers:

Adjustments to the thousandth of an inch can be made in less than a minute. In fact, the Wetmore is the quickest and easiest adjusting reamer made. Cone expansion nut keeps blades always parallel with axis.

Solid, heat-treated alloy steel body guaranteed against breakage.

Left Hand Angle Cutting Blades that prevent digging in, chattering, and scoring of the reamer while backing out. Shearing effect of blades increases life of cutting edge.

No grinding arbor required for regrinding. Wetmore Reamers can be reground on their original centers.

Write for your copy of the Wetmore Hand-book—a valuable reference work for precision tool users. Sent free, postpaid, on request.

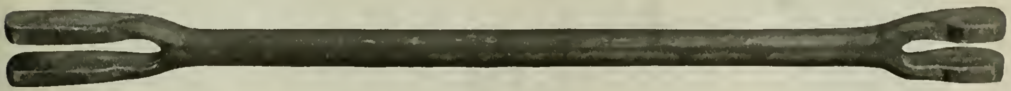
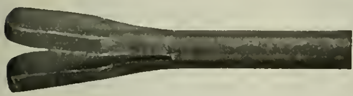
AJAX

(Trade Mark Registered)



A



B

WELDLESS Bottom Connections at Rate of 300 per 9 Hours

Weldless Bottom Connections are being produced by an Ajax Upsetting Forging Machine and Ajax Hot Saw more rapidly and economically than the inferior welded rods.

Bottom connections have been made for years by welding forged jaws or "U" pieces onto rods of the required length. Production seldom exceeds 125 or 150 complete rods per day and defective welds cause frequent breakages.

Weldless bottom connections are, as the name implies, made from one solid bar of steel of the required size without weld. The stock used is brought to good forging heat on the end and given a preliminary upset A in the forging machine. It is then passed to the hot saw for slitting B and returned to the forging machine, where the jaw is formed in a single operation. All this is done without re-heating.

A crew of three men produce more than 600 ends, i. e., 300 complete weldless rods, in a 9-hour day without difficulty, ***cutting the labor cost in two and yet giving a superior product.***

For producing jaws and "T" head forgings the Ajax Hot Saw and Burring Machine is a most valuable auxiliary to the Upsetting Forging Machine. Write for our descriptive Bulletin No. 28-A.

Colton-Detroit Twist Drills

You Are Buying Holes—or Drills?

If you buy a motor car, you are really buying mileage. If you buy Colton-Detroit Twist Drills you are buying holes—the most holes per dollar of cost.

You have never had drills like Colton-Detroits. They are not milled—they are forged from special steel in accurate dies. Match them with what you are now using.

Colton-Detroit quality at fair prices is something you can't overlook. Point for point, there is no drill value on the market superior to Colton-Detroit. Ask for facts.

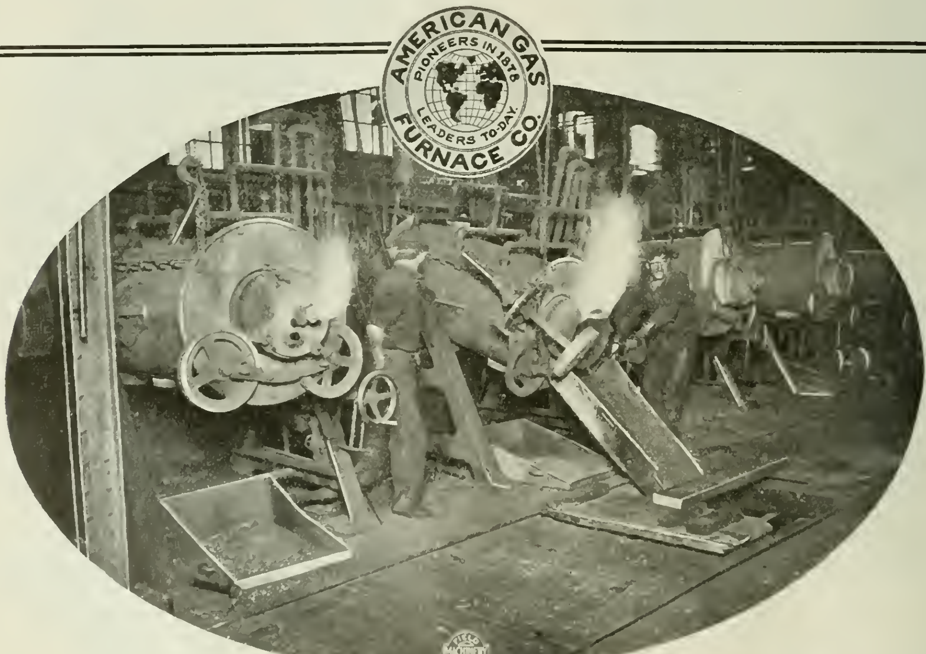
Parts for Baldwin Chains Are Carbonized in

American Rotary Gas Furnaces

Before the Baldwin Chain & Manufacturing Company, of Worcester, Mass., installed this battery of American Gas "Rotaries," pins, rollers and other parts for its famous chains were packed for several hours in containers, placed in a furnace, and afterwards quenched. For the last four years, however, they have been merely loaded into the revolving retort of American Gas Furnaces—about 350 lbs. per load—and rotated for 2½ hours; then tipped into a quenching tank, as shown. Gas burning between the retort and the interior of the furnace brings the work rapidly to the correct temperature and automatic heat control maintains it at uniform temperature throughout the entire operation; while from carbon gas, passing through the retort, carbon is absorbed by the tumbling pieces to a more uniform depth on all surfaces than could be obtained by the old method.

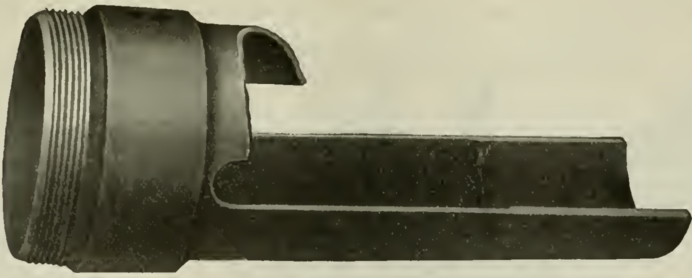
There are eight of these machines in the "Baldwin" installation—clean, compact, easy to operate and entirely dependable. American Gas Furnaces cover all heat treating requirements—from tool room to rolling mills—and our service department will be glad to discuss their respective advantages in connection with your work.

Our line includes: Gas Furnaces, Carbonizing Furnaces and Machines, Pressure Blowers, Heating Machines, Automatic Heat Controllers, Forges, Cylindrical and Oven Furnaces and every type of Gas Blast Furnace and Heating Machine for Industrial Uses.



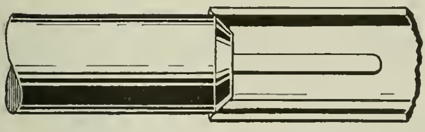
AMERICAN GAS FURNACE COMPANY

Main Office and Works: ELIZABETH, NEW JERSEY

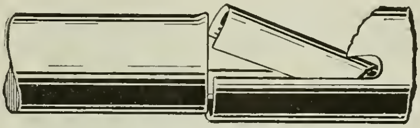


This feed finger was broken by a burred rod

This accident stopped production for 25 minutes and caused a loss of $12.50 for replacing feed finger. It would not have happened with Bridgeport Ledrite Brass Rod because all Ledrite rod is chamfered on the ends.



The Ledrite chamfered end eliminates danger of broken feed fingers.



This shows how a burred rod broke a feed finger.

Ledrite Rod as made by Bridgeport Electric Furnace processes, in addition to being chamfered at both ends, is the best free-cutting composition, a composition which is accurately maintained by testing. No screw machine spindle speed is too high for Ledrite Rod. Ask for our Brass Rod Book No. 1439.

U-LOY STEELS

From the Electric Furnace

A heavy switch is thrown—electricity of enormous power is released. An arc forms between the electrodes and the charge. Soon melting takes place.

So intense is this arc that it refines steel to a higher degree of purity than any other method. The injurious effects of sulphur and phosphorus are reduced to a minimum. Impurities are removed. Greatest freedom from surface and sub-surface defects is insured. In purity, uniformity and homogeneity U-LOY Electric Furnace Steels are far superior to even the best open hearth steel.

Perhaps U-LOY Electric Furnace Steels would improve your product—*no matter what it may be.*

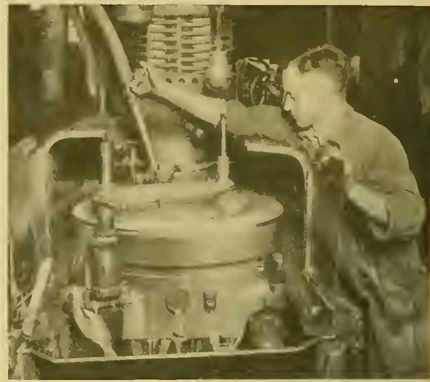
Grinding in the Industries

The second of the series of five grinding articles to be published under the general title "Grinding in the Industries" appears in the editorial pages of this number of MACHINERY. This series will show by actual examples the remarkable development of grinding practice in our big industries, including the automotive, small tool, railway, foundry and steel mill.

The advancement in the modern art of grinding has been so fast that intensive study must be given every new machine, improvement or method. The advertising which follows this page is the grinding machine, grinding wheel and grinding accessory manufacturers' contribution to further general knowledge of the most up-to-date methods in this rapidly developing field. In these specially prepared advertisements you will find data, pictures and examples of grinding work that will probably cause you to get out a pad and pencil and work up some figures of your own, and when an advertisement does this it has accomplished its mission.



The Right Abrasive, a Sufficient Wheel
Stock, Experienced Men Mean

Grinding Wheel Service

There are two main reasons for the success of Norton grinding wheels on every kind of grinding and under the many varieties of conditions:

1. Different kinds of abrasives, different bonding processes, and a great variety of grains and grades from which to select the wheel that will perform properly.

2. Knowing how to select the abrasive, the process and the grain and grade.

Briefly there is a Norton wheel made of the right abrasive for every condition of grinding; there are in the Norton Administration Building great quantities of data accumulated from experiences of demonstrators under many conditions, and there are Norton men who have a knowledge of grinding that enables them to select wheels of correct abrasive, bond and grain and grade.

You may be operating with a tremendous waste if you are using the wrong wheels on the job.

ALOXITE "AA"

The Wheel for

The Aloxite "AA" wheel represents the greatest advancement in grinding wheels for tool-room work that has been made in years.

It is a wheel of unprecedented freedom of cut—a wheel that stays sharp, stands up to its work and cuts cool.

It is a wheel that responds admirably to the control of the operator taking light cuts or heavy cuts, within the range of practical tool-room work, without burning or distorting the piece. Another advantage in using Aloxite "AA" wheels is found in the fact that they can be made in very soft grades and still they will not wear away rapidly. Aloxite "AA" wheels will increase tool-room production because they will turn out better work—quicker.

It wasn't possible to make such an ideal tool-room wheel from the ordinary aluminous abrasive. Many months of exhaustive research and study told us this. The development of a new abrasive was necessary so Aloxite "AA"—the abrasive for tool-room wheels—was the result.

"A

The Carborundum Company, Niagara Falls, N. Y.

New York, Chicago, Boston, Philadelphia, Detroit, Cleveland, Pittsburgh

ALOXITE "AA"

the Tool-Room

This new abrasive is 98½ to 99 per cent pure alumina and its crystals are one hundred times larger than those of the average aluminous abrasive.

Because of the almost total exclusion of impurities from the abrasive grain, Aloxite "AA" wheels cut without drag or creating undue friction.

Because of the extraordinary size of the Aloxite "AA" crystals, each grain in the wheel is a definite fragment broken from the larger mass, thus assuring a grain with a sharper, cleaner fracture, again resulting in a cleaner, cooler cutting wheel.

Then, too, Aloxite "AA" wheels have an open, porous structure. Each grain gets a real chance to cut—to penetrate the work, removing the stock amazingly quick and leaving a uniform finish.

For the grinding of alloyed and high speed steel reamers, cutters, drills, hob mills, and similar tools, for work on hardened steel surfaces, for all of the internal work on bushings, bearings, gauges, etc., Aloxite "AA" is distinctively the wheel for tool-room work—a wheel of astonishing performances.

Try Aloxite "AA" in your tool-room. You have never had a wheel so genuinely efficient.

A"

The Carborundum Company, Niagara Falls, N. Y.

Cincinnati, Grand Rapids, Milwaukee,
Manchester, England.

"PRODUCTION"

POLISHING and FINISHING MACHINES

(Patented)

This machine will do all grades of cylindrical finishing from ordinary one pass work to the finest buffing on brass, etc., using special felt belts.

The centerless feed gives speed. Why not let us tell you what "Production" machines will do for you? Write for descriptive data.

PRODUCTION MACHINE CO.

40 Seconds to Pass a 10 Foot Tube Through this Machine —No Centering, No Chucking —Just Feed Automatically

This is one of three "Production" Polishing and Finishing Machines in the Hartford, Conn., plant of the New Haven Sherardizing Company. The process of Sherardizing iron or steel consists in coating the metal with a zinc veneer to prevent rust and corrosion.

The New Haven folks do a lot of this work, particularly on tire formers for shaping and making inner tubes.

These moulds are made in various diameters from seamless steel tubing—those in the picture are 3¼″ diameter by 10 feet long. They are placed in a channel guide and automatically fed against the surface of the swift-moving "Production" belt. The action rotates the tube and polishes at the same time. Different grit belts perform different polishing operations on each tube. It requires 40 seconds for a tube to go through the "Production" polisher once, and you get a uniform mechanical finish always the same—no chatter—no flats.

Once More BESLY Grinding Beats Milling

Photo and data concern the production problems at Platt Iron Works, Dayton, Ohio, where the application of Besly Grinding is being extended as fast as is practicable.

520

Six to One

is the latest official record of its output as compared to milling on the valve decks for steam pumps here shown in process of grinding. This is a surfacing job and not more than eight to ten per hour were produced on the miller, whereas the "Besly" tripled production at the first go and soon showed that 60 per hour was a reasonable output to expect.

This machine has been four years at the Platt Works where additional "milling" jobs are being transferred to the grinding department as fast as the simple fixtures necessary can be designed and built. Many require no fixtures at all, for the Besly Geared Lever Feed Table (Patented) with which the machine is equipped has many features which facilitate setting up without further equipment—among them a highly sensitive hand feed adjustable by micrometer stop screws graduated to .001″. Top of table may be tilted 30° from horizontal and has vertical adjustment as well. It is provided with T-slots and may be further equipped with angle plates and a Universal Bevel Protractor.

Besly Grinders require no skill to operate — another saving to their credit—and maintenance cost is negligible. Details in Catalog—Advice on receipt of specifications or samples of "that expensive job."

BESLY

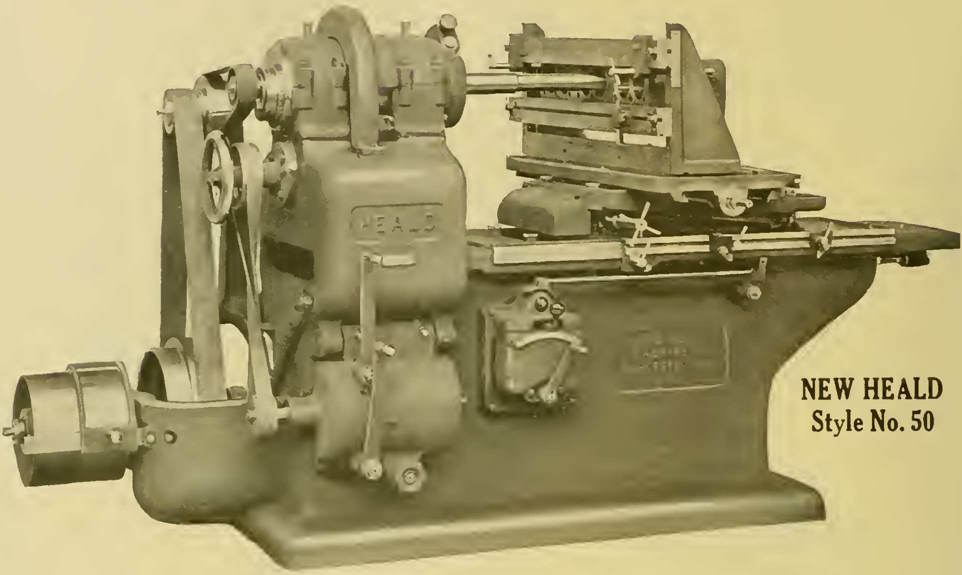
CHARLES H. BESLY & COMPANY

120-B N. CLINTON STREET CHICAGO, ILL., U. S. A.

Buyers of Motor Cars Now



NEW HEALD
Style No. 50

Simple – Massive—Large Capacity—Practically Gearless —Unlimited range of speeds for the table which can be reversed or stopped at any point without shock or noise.

The general buying public and motor mechanics are fast becoming thoroughly educated and convinced of the merits of a ground cylinder in comparison with one that has been bored and reamed. Sales agents everywhere have found that the preference is for cars with ground cylinders.

While it is a well-known and accepted fact that all high grade auto manufacturers finish their cylinders by grinding, few realize how many of the less expensive car builders are also using this operation to give greater efficiency to their motors.

Such manufacturers as Dort, Essex, Gardner, Grant, Hupmobile, Jewett, Rickenbacker, etc., have long realized its advantages and now find it to be a big factor in their sales arguments. Taking all the car manufacturers, both pleasure and commercial, about 90% finish their cylinders by grinding.

Insisting on Ground Cylinders

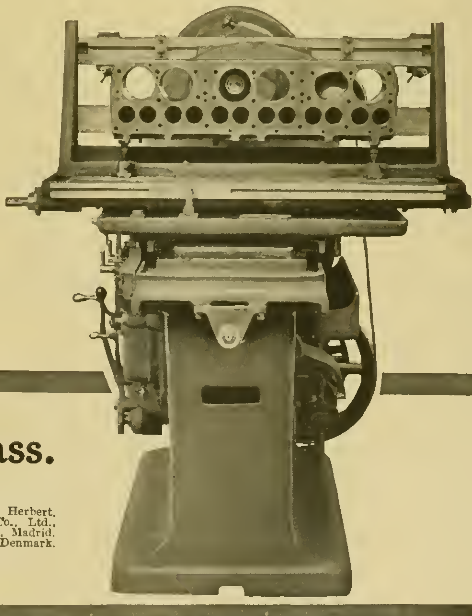
It is interesting to note that Chandler have just equipped with Heald machines and will hereafter furnish motors with ground cylinders.

Undoubtedly a good share of the reason why the public is insisting on ground cylinders is due to the fact that there are 1400 Heald machines in this country doing nothing but regrinding and fitting new pistons and rings. This has without question been a tremendously big item in educating motor owners to the advantages of ground bores in regard to economy and efficiency of operation, and is especially true with those whose cylinders were originally bored but have been reground for they can more easily appreciate the difference.

Level-headed engineers and mechanics in such plants as Rolls-Royce, Packard, Pierce Arrow, Cadillac, Locomobile, Peerless, Stutz, Winton, Cunningham, etc., realize that only by grinding can a true, round hole be obtained and one which will be absolutely at right angles to the flange, giving a perfect bearing to the piston.

They have also unanimously agreed upon the Heald Machine as the best to do this work. Heald machines have been for seventeen years used expressly for grinding cylinders and the latest model, Style No. 50, is especially desirable for manufacturing purposes. It is unusually heavy and rigid, self-contained, with an hydraulic drive for the table enabling the operator to get any speed, from nothing up to the maximum, or can be reversed and stopped at any point without shock or noise.

The illustration below shows the Heald No. 50 grinding the bores of a Hudson Super-six. Note the massiveness of the bed and width of the table.



We would like to furnish you with a bulletin fully explaining the new Heald Machine. How many shall we send to take care of all your interested executives?

BROWN & SHARPE PLAIN GRINDING MACHINES

A new angle on the Economy of Grinding

Quantities of jobs demanding either high accuracy or smooth finish and now being completed on automatics or turret lathes can be finished with greater economy by grinding.

By giving pieces an allowance for grinding, production is increased on the automatics, turret and engine lathes which are no longer held to the feeds and speeds necessary for high accuracy and smooth finish.

The grinding machine keeps pace with this increased production and turns out smoother, more accurate work than can be secured by other methods.

Thus Quantity is increased and Quality improved by finishing work on a grinding machine.

For a truer surface, more uniform size, and a smoother finish at less cost use Brown & Sharpe Grinding Machines.

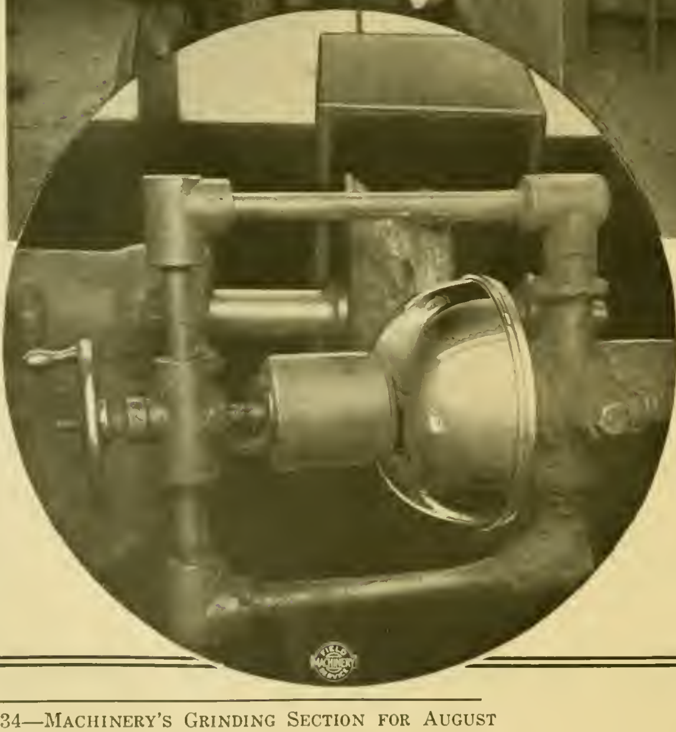
Send for Catalog No. 137 describing our complete line of grinding machines.

AUTOMATIC BUFFING MACHINES

Eighteen—Busy All the Time

Competition is keen in the aluminum ware business and every saving in production costs means lower prices and better sales. In this case the Automatic Buffing installation has not only reduced manufacturing expenses and about doubled production, but has improved the quality of work.

The work shown is a colander—output 800 in 9½ hours—one operator, two machines.



Let us give you further details—tell you something about the wide range of work possible with our new machine.

GRINDING LUBRICANT

"Economy" Clinches All Arguments

This "close-up" in a famous motorcycle manufacturing plant shows the internal grinding of clutch pinions. A 3/4″ hole is being ground to size. The grinding wheel is 5/8″ diameter and to attain a suitable surface speed it naturally makes more revolutions than would a larger wheel. It is also true that any given point on the wheel makes contact with the work more often than any point on a larger wheel. There is more wear with the small wheel and therefore greater tendency to clog; *but it does not clog* for the Grinding Lubricant is "Economy."

"Economy" is the efficient lubricator. It prevents clogging. It keeps the wheel and work cool. It earns its name by its thrift. This is not an isolated case—"Economy" will do as much for you as it does for others.

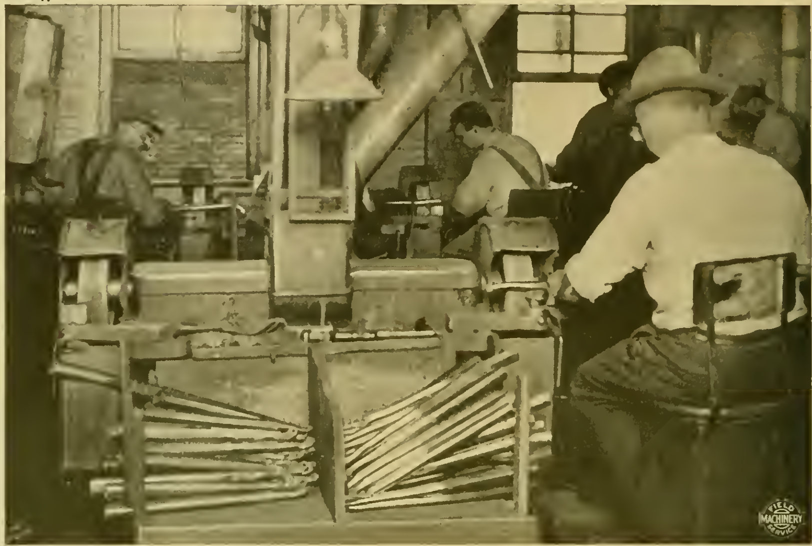
Divine Polishing Service



Finishing Top-Bow Sockets

The Brewer-Titchner Corporation, Binghamton, N. Y., manufactures automobile hardware. Among its products is the bow socket for one-man type automobile tops. Compare the quality of this socket with the article used a few years ago on five and six-bow tops. Brewer-Titchner has achieved a triumph in this socket. It is made in two pieces. One piece is No. 20 gage sheet steel formed to the desired cornucopia shape, and the other a steel forging. The two are welded together.

In a welding operation of this character there is considerable surplus metal and scale on the surface. This must be removed and that is just where *Divine Brothers' Polishing Service* comes in. For 5 years ten spindles in this shop have been equipped with Divine Wheels—14″, compress canvas, charged with grain 36 alundum. Production is fast and the work high-grade.

Let us tell you more about Divine Polishing Service.

DIVINE POLISHING SERVICE

Divine Polishing Service consists of:—

1—*Studies of polishing problems of all kinds.*

2—*Recommendations* based on thirty years' engineering experience.

Everything For The Polishing Room

DIVINE BROTHERS COMPANY, Utica, N. Y.

Metal Finishing Engineers

—And All the Way Between

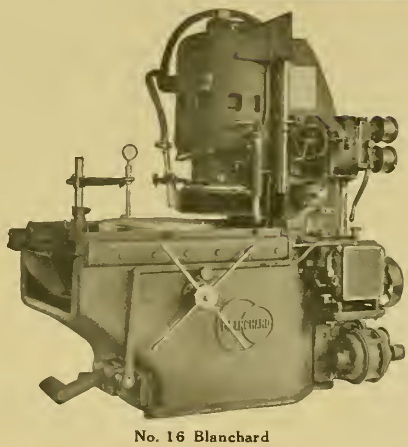
The Blanchard Grinder, almost since its inception, has been used for grinding ball races. This industry was one of the first to realize the production possibilities of the Blanchard Grinder; and now, there is scarcely a concern which manufactures ball or roller bearings and does not use this machine.

Roller Race 21½" O. D.

These small ball races are ground 875 at a time upon the 26″ one-piece steel magnetic chuck.

One man operating the machine produces 700 pieces per hour; but, with improved facilities for washing and handling, one man and helper turn out 3600 pieces (7200 surfaces) per hour.

Ball Race ⅝" O. D.



No. 16 Blanchard
High Power Vertical Surface Grinder
Direct Motor Drive Type

This story is not complete unless the new No. 16 Blanchard Automatic Surface Grinder is mentioned. This new machine, illustrations of which are not yet available, is designed for large quantity production of pieces 6″ diameter or smaller.

On rings of medium size, the Automatic with one operator produces approximately twice as many pieces per hour as the standard No. 16 Blanchard Grinder with operator and helper.

FAFNIR

Fafnir Ball Bearing Tool Grinders are made to run all the time—right from the main line.

You know how it is with tool grinders;—everybody uses them, nobody takes care of them, but everybody kicks if they aren't in good condition. They are usually left running, almost never oiled, the bearings wear and they become an infernal nuisance.

You can relieve yourself of all this trouble and worry by buying *Fafnir Ball Bearing Tool Grinders.* The spindle is mounted on alloy steel *Fafnir Ball Bearings.* They are designed to be run constantly from any line of shafting without counters or loose pulleys; they require only a few drops of oil once in several weeks, and will last indefinitely.

Our new catalog of *Fafnir Industrial Ball Bearings* is now ready for distribution.

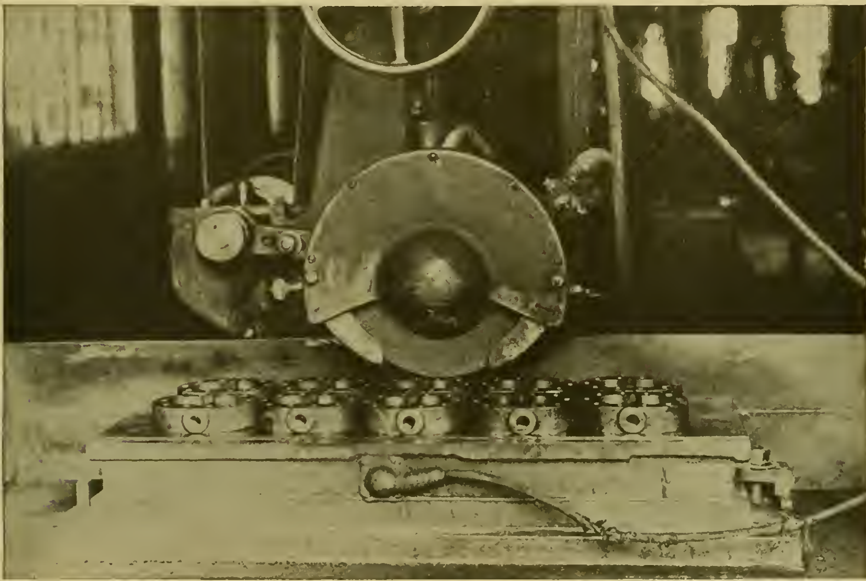
Grinding Metal-to-Metal Joints on a
DIAMOND SURFACE GRINDER



Above is a typical "Diamond" Surface Grinding job, handled with true "Diamond" efficiency throughout—bodies for high pressure oil pumps, rough and finish ground on both sides, 10 at a time, at the rate of 10 completed bodies in 90 minutes.

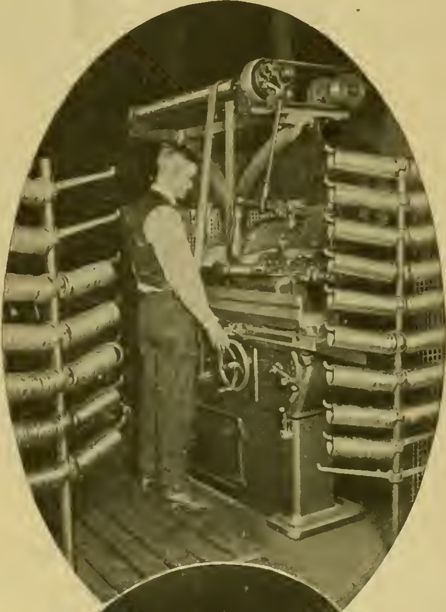
No gaskets are used in joining the bodies to the backs and the joint must withstand a pressure of 1000 lbs., so limits are necessarily very close—.015″ of metal being removed by the roughing cut and .0015″ in finishing. Material is gray cast iron and the pieces are 5½″ by 4″ overall.

The "Diamond" Line is complete: Surface Grinders in many styles and sizes, Face Grinding Machines—a complete range; Water Tool Grinders, Disc Grinders, Floor Grinders, Swing Frame Grinders and Polishing Machines—a machine for every grinding need. Catalog on request.

DIAMOND MACHINE COMPANY
PROVIDENCE, RHODE ISLAND

MODERN

Grinding Piston Rings is a Two Man Job Here; But They Find it Profitable, at That



At the Burd High Compression Ring Company's plant, Rockford, Ill., this Modern Grinder is used regularly 10 hours every day on the same job—rough and finish grinding 3″ by 3/16″ piston rings, *44 at a time.*

Speed is 126 ft. per minute; so fast, in fact, that it keeps one man busy loading and unloading duplicate arbors while another gives his entire attention to the machine.

The first operation removes 0.005″ of stock, and is performed at the rate of 3600 rings per day. Finish grinding reduces the diameter from 3.015″ to 2.995″ —allowing 0.001″ for heat expansion— and output is 3200 in the ten hours.

Modern Grinders have made similarly interesting records in many fields. Powerful, rigid, and smooth-running, they assure unfailing accuracy and a profitable output on any grinding operation within their broad and practical range.

Let us tell you about them.

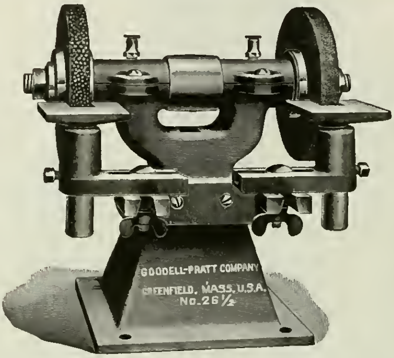
1500 GOOD TOOLS



Polishing and Grinding Heads

Every shop, small or large, has use for little Polishing and Grinding Heads in many places. Our line of these useful little devices has so many different styles that every user can find one adapted to his needs.

The Frames are made of iron with hollow Bases so that they will be as light as possible. The Spindle Holes are reamed and counterbored. Both Spindles and Collars are lathe turned so that they will run accurately.

All sizes of these machines are provided with adjustable Boxes. The Pulleys will all take flat Belts, but the smaller sizes are grooved in order that round Belts may be used if desired.

A number of these Polishing Heads are provided with three jawed Chucks which greatly increase their field of usefulness.

All iron parts are finished in red and black enamel; steel parts are polished.

Full specifications of these Heads in our No. 14 Tool Book; complete copy of which we will be glad to send you upon request.

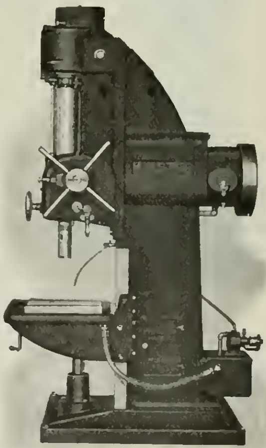
Minster Hi-Duty Drills

Powerful—Productive—Profitable

The weight, power and operating convenience of Minster Drills make them the ideal machines for heavy drilling in solid steel; while the balanced construction and fine adjustments (so easily made) make these big machines equally valuable on finer work. A working range that with great capacity guarantees them an exceedingly profitable investment in any big machine shop.



Three sizes—to drive drills to 2", 2½", 3¼" in solid steel.

FOSDICK DRILLING MACHINES

Always Better than the Work Demands

In the 34 years of our drill manufacturing experience we have consistently kept Fosdick Drills just a little ahead of the standard requirements for machines of this type—always ready to meet the advancing standards in drilling practice.

The cuts show:—the Fosdick High Speed Ball Bearing Sensitive Drills, 16″ to 24″ swing, in combinations of one to eight spindles; Fosdick Radial Drills, made in sizes ranging from 2 to 6 feet.

Seventeen Years Without Repairs!

THE "GIANT" Keyseater

Send for a detailed description of the machine; let us give you other records for service and tell you something about production and operating costs.

Installed seventeen years ago, in constant operation and *no repairs!* Some record in these days of strenuous production. Working records like this are made possible by simple, durable construction and easy operation. Accuracy is assured by the work holding method. The grooved post which holds the work by its bore also forms a guide for the tool bar supporting it through its entire length and preventing spring.

"GIANT" Keyseaters are made in eight sizes; long wearing, profitable machines whether used for production manufacturing or single operation work.

Piecework Lags too without Counters

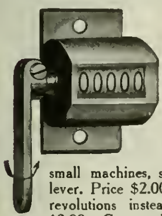
At machines where the worker is paid by piecework, "going slow" is almost as prevalent as in day work. Unless—

You measure or count the output with a Veeder Counter—which indicates not only the amount actually done but the amount which **ought** to be done.

Piecework or day work are equally subject to improvement, when

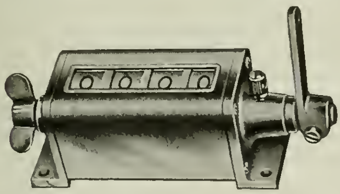
Veeder COUNTERS

show the *should-be* production and how well the worker maintains it, hour by hour.



This small **Rotary Ratchet Counter** (No. 6) counts reciprocating movements of the lever, as required in recording the product of many small machines. When the lever is moved through an angle of 40 to 60 degrees, the counter registers one. A complete revolution of the lever registers ten. This counter is adaptable to no end of small machines, simply by regulating the throw of the lever. Price $2.00. Small *Revolution* Counter, to record revolutions instead of reciprocating movements, also $2.00. *Cut nearly full size.*

The **Revolution Set-Back Counter** below is designed for the larger machines where a shaft-revolution indicates an operation.



Registers one for each revolution of shaft, and sets back to zero from any figure by turning knob once round. Supplied with from four to ten figure-wheels, as required. Price, with four figures, as illustrated, $10.00—subject to discount. (Cut ½ size). Set-Back Rotary Ratchet Counter, to record production of punch presses, etc., price $11.50 —subject to liberal quantity discount.

Write for booklet showing Veeder developments in counters; all kinds for your requirements are there.

CHAMPION

Your product is as reliable as the parts of which it is made. If a vital part fails it stops. Ceasing to produce, it earns nothing. It becomes an expense to your customer. His men are idle and costs rise.

Drop forged load bearing and strain resisting parts are vital. Machine productiveness depends upon it. By the use of Champion Drop Forgings you may achieve:

The tough, sturdy, give and take strength of steel where stamina is vital.

Lighter weight and less bulk.

One-third reduction in machining and finishing time.

Elimination of loss from breakage of tools and parts in handling resulting in economies which more than repay you the slightly higher first cost of forgings.

Hundreds of different parts can be forged by Champion. You want business then you will appreciate the cooperation of a Champion Engineer—a practical business man and productive executive who will study your problem intimately with your engineers. His services are available on request. Name the time he may prove to you the soundness of these claims.

SAVING A FEW CENTS PER POUND

Saving a few cents per Pound by buying babbitt which lasts only half as long as Ajax Bull Bearing Alloy, is not economy. It's sheer waste.

The babbitt itself is a minor item in the expense of rebabbitting. It's the time and production you lose while the machine is shut down. Labor costs don't stop, overhead keeps on piling up. Nothing goes down but the net profits.

AJAX BULL BEARING ALLOY

wears longer than any babbitt metal because it's made of virgin metals by the Ajax Alloying Process.

It's all in the Ajax Alloying Process.

FRANKLIN DIE-CASTINGS

Best for Bearings

Not only in automobiles, but also in stationary engines, compressors, automatic pumps, etc., Franklin Die-Cast bearings represent a big advance over the old method of babbitting the shaft.

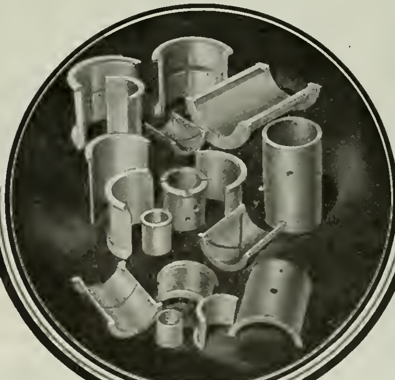
They give better service than machined bearings, being equally accurate, more uniform, quicker to interchange (no metal to pour) and harder (chilled under pressure).

They lower costs in assembly, upkeep and replacement. They require no machine operations save those customary in assembling even the most fully machined bearings—line-reaming, scraping, burnishing, etc.

The babbitts used include the S. A. E. standard formulas, together with others proved by Franklin's 30 years of experience.

Let us solve your problems. We quote from samples or blueprints. Send for booklet: "Franklin Die-Castings in Modern Inventions."

FRANKLIN DIE-CASTING CORPORATION
Gifford and Magnolia Streets Syracuse, N. Y.



"THE HOUSE OF HAWKRIDGE"

The use of Hawkridge Steel for all purposes for which high grade steels are essential has become so general in this part of the country during the past 38 years that it is fast assuming the dignity of a habit among New England steel users. "Cooperation" is our motto; and watchmakers, spring makers, small tool makers, hospitals, electrical supply houses, machine tool builders, quarries, mines, cutlery companies and many others have benefited at one time or another by our far-sighted selling policy, which gives the salesman as much credit for advancing the interests of a customer as for selling a car load of Hawkridge Steel.

Our line is complete and includes the Best High Speed Steel made, the freest cutting Machinery Steel, Crucible Tool Steel (including the "Hawk" Brand). Oil-hardening or Water-hardening, Hot-rolled or Cold-drawn, High Carbon or Low Carbon, Rough-turned or Drill Rod finish, Heat-treated or Annealed, Alloyed or just plain Steel—in Rounds, Squares, Hexagons, Octagons, Quarter Octagons and Special Shapes.

Drive It With DIAMOND Chains and Sprockets

For practically every place where power is transmitted—whether on a light, high speed electrical device, or on a heavy, slow speed machine tool — DIAMOND Chains and Sprockets provide dependable power-drives that meet every demand of efficiency and economy. They save power, and speed up machinery, because slippage is eliminated and friction reduced. They avoid shutdowns and save repair bills by giving constant, durable service.

They are extensively used by mills, mines, factories, power plants, railroads, etc.—daily demonstrating their ability to reduce costs of power and maintenance, and increase the output of machines they serve.

In the DIAMOND Line are more than fifty standard chain models—ranging from $\frac{3}{8}$ to 2 inches in pitch, and from $\frac{1}{8}$ to $1\frac{1}{4}$ inches in width. This offers you correct chains for all transmission requirements, no matter how high the speed or how heavy the load.

And whatever size or type of sprockets you require, the DIAMOND Sprocket department is well equipped to serve you. Where special chains are required, we can produce standard roller or block chains with special features to meet your needs.

To aid you in selecting the chain and sprockets best suited to your drives, we offer the services of our engineers, who have had years of specialized experience in solving transmission problems.

We have a handy-size, loose-leaf book "Useful Data on DIAMOND Chain Drives." You'll find it of real help in ordering DIAMOND Chains and Sprockets. Write for it.

In the Final Analysis——Cast-Iron Pulleys

Have you ever thought of the pulley troubles you have had and how invariably the drive was made satisfactory by installing Cast-Iron pulleys—either supplanting pulleys of some other type or by changing to cast-iron pulleys of suitable construction?

BUT IT WAS A CAST-IRON PULLEY THAT FINALLY STOOD UP UNDER THE SERVICE

Almost every user of power has had this experience and always the solution of continuously satisfactory transmission service has been the installation of cast-iron pulleys.

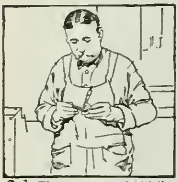
The use of cast-iron pulleys in the initial installation will prevent trouble.

T. B. WOOD'S SONS CO., Chambersburg, Penna.

POWER TRANSMITTING MACHINERY

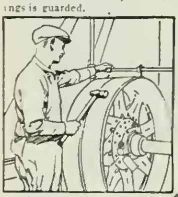
AMERICAN STEEL SPLIT PULLEYS

1st Careful laboratory work watches the fitness of the steel itself.



2d The micrometer faithfully guards the uniform correctness of jigs, dies and tools.

3d This test picture shows how the accuracy of bushings is guarded.



4th Guarding circumferential accuracy. Lasting trueness is assured by a series of such tests.

Uniformity of Service

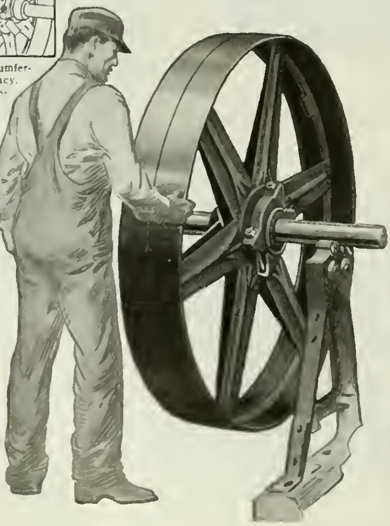
THIS essential condition of pulley efficiency is safeguarded by a long series of scientific and practical tests in the manufacturing process of "American" Pulleys. These tests make certain that each "American" Pulley is as true and perfect as every other "American."

And, in turn, this assured uniformity must be one of the major reasons why nearly six million "American" Pulleys are now in operation, both here and abroad.

A book entitled "Getting Maximum Pulley Efficiency" will be mailed you on request, at once.

The American Pulley Co.
Philadelphia, Pa.

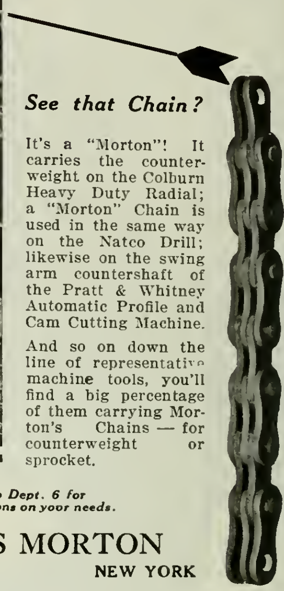
Manufacturers of Steel Split Transmission Pulleys, Steel Sash Pulleys and Pressed Steel Shapes



For complete list of distributors see MacRae's Blue Book

MORTON'S CHAINS

for
Machine Equipment



See that Chain?

It's a "Morton"! It carries the counterweight on the Colburn Heavy Duty Radial; a "Morton" Chain is used in the same way on the Natco Drill; likewise on the swing arm countershaft of the Pratt & Whitney Automatic Profile and Cam Cutting Machine.

And so on down the line of representative machine tools, you'll find a big percentage of them carrying Morton's Chains — for counterweight or sprocket.

Write to Dept. 6 for quotations on your needs.

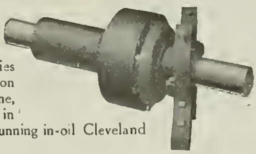
protects itself from all dirt

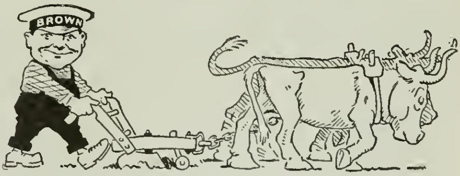


DIRT and dust, enemies of smooth operation and long life in any machine, are never given a chance in the entirely enclosed, running in-oil Cleveland Clutch.

Let us tell you more about it

Cleveland Clutches

THE RELIANCE GAUGE COLUMN CO.
6008 Carnegie Ave. Cleveland, Ohio



Good for Hard Pulling

Kanti - Lever Spring Couplings enable your motors to pull hard loads with ease. By correcting misalignment they cut down bearing pressure and reduce friction. Through their spring-spoke driving system they prevent shocks and jars from reaching your motors, thus smoothing out the load curve and cutting down the cost of motor maintenance.

"NORMA" PRECISION BALL BEARINGS

In machines, and in parts going to make up the complete machine, the factors which will determine the difference between satisfactory service and dissatisfaction seldom reveal themselves to superficial examination. That difference lies in the intangible elements broadly comprehended in the word "quality."

All good ball bearings look very much alike. The vital differences determining values become apparent only under the tests of service. The performance records of "NORMA" Precision Bearings in high-speed, high-duty, high-service machines reveal the quality which recommends these bearings preeminently for this exacting class of work.

Our engineers will welcome an opportunity to work with yours

PHILADELPHIA GEARS

Take a look at the bird's-eye views of Phillie Gear's whole plant, and remember that the business was started only 30 years ago—the first exclusive gear making plant in the country—and has attained its present proportions solely on the merits of the service it provides.

Doesn't it indicate that this service is truly essential? And well appreciated? Doesn't it suggest that it would be a good thing for *you* also to send your gear orders to Phillie Gear?

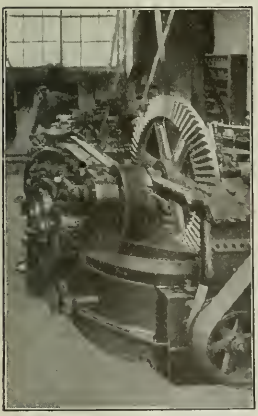
Pinions to
Mill Gears—
any size and
in any quantity.**



Phillie Gear's Catalog is a Regular Treatise on Gears—Yours for the asking.

"Speed" is Phillie Gear's middle name; but he doesn't use it in business, for fear of misleading people who do not know that "accuracy" heads the list of "musts" in his shop.

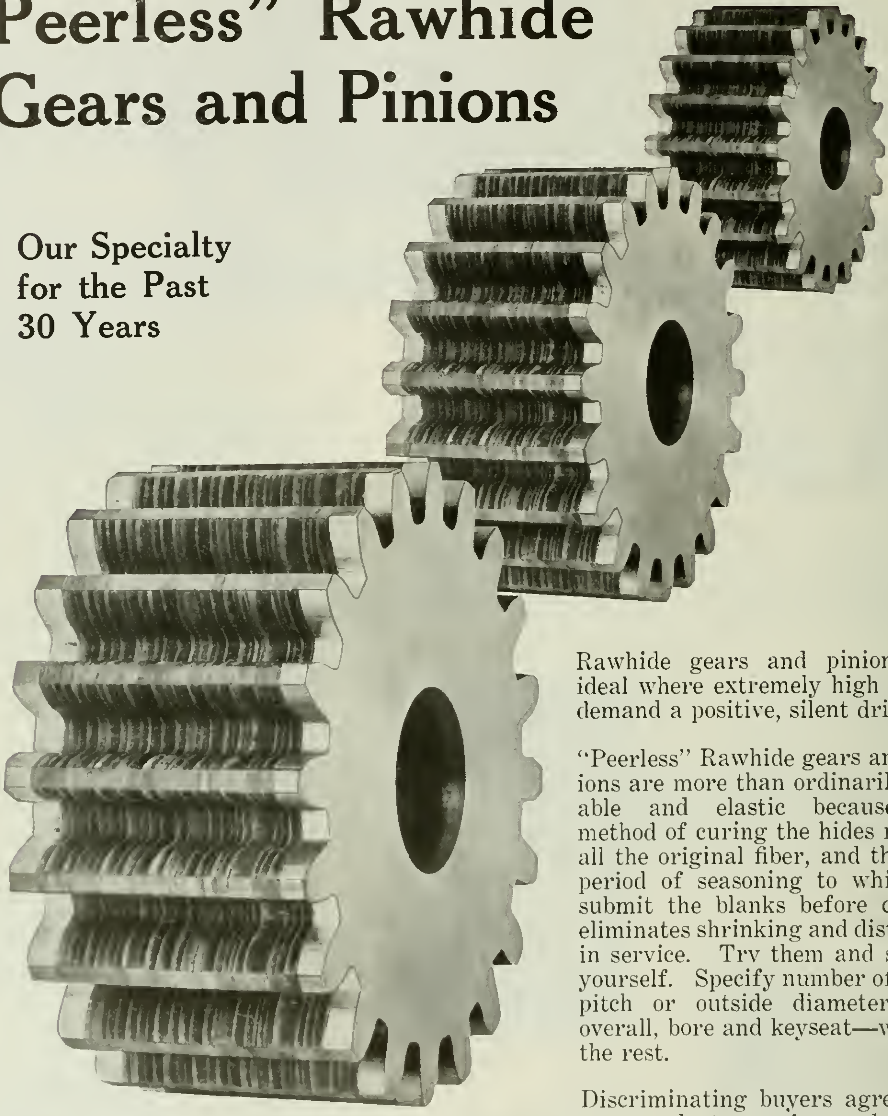
His fondness for speed shows itself in the absence of red tape, in the accessible arrangement of his enormous stock of "ready to ship" gears and in the care with which he schedules the work so that every man and machine make "every second count."

Philadelphia GEAR Works 1120-1128 Vine St. Philadelphia

MEMBER OF AGMA

"Peerless" Rawhide Gears and Pinions

Our Specialty
for the Past
30 Years



Rawhide gears and pinions are ideal where extremely high speeds demand a positive, silent drive.

"Peerless" Rawhide gears and pinions are more than ordinarily durable and elastic because our method of curing the hides retains all the original fiber, and the long period of seasoning to which we submit the blanks before cutting eliminates shrinking and distortion in service. Try them and see for yourself. Specify number of teeth, pitch or outside diameter, face overall, bore and keyseat—we'll do the rest.

Discriminating buyers agree that our product, service and prices are right.

We also manufacture metal gears ¾ inch to 12 feet.

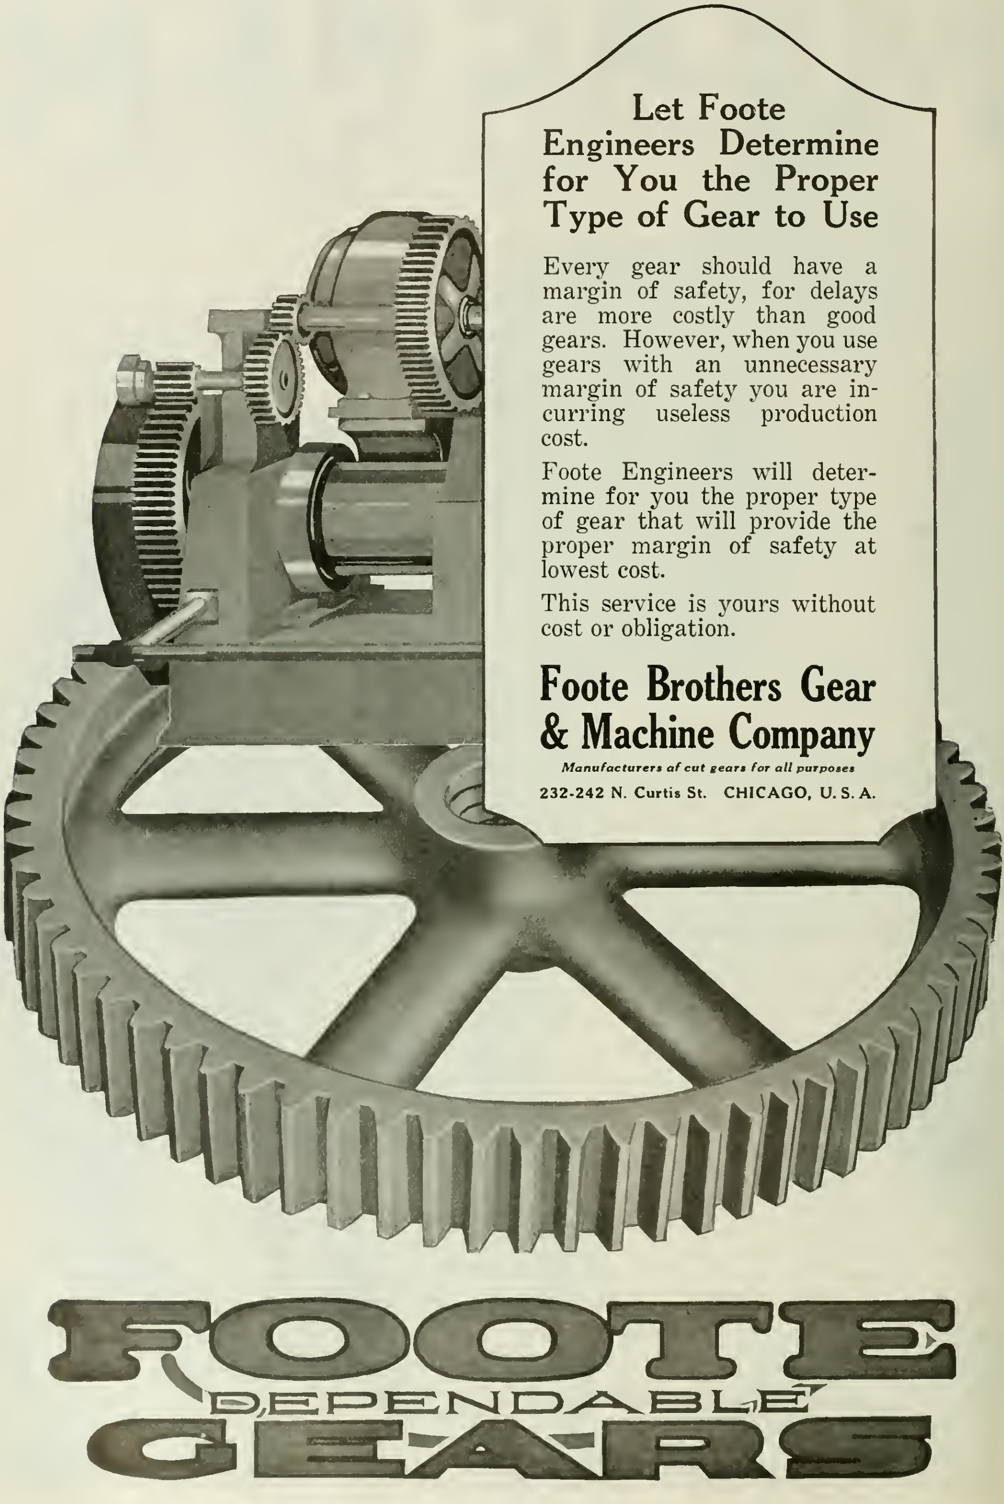
THE HORSBURGH & SCOTT CO.

CLEVELAND, OHIO, U. S. A.

MEACHEM



Let Foote Engineers Determine for You the Proper Type of Gear to Use
Every gear should have a margin of safety, for delays are more costly than good gears. However, when you use gears with an unnecessary margin of safety you are incurring useless production cost.
Foote Engineers will determine for you the proper type of gear that will provide the proper margin of safety at lowest cost.
This service is yours without cost or obligation.

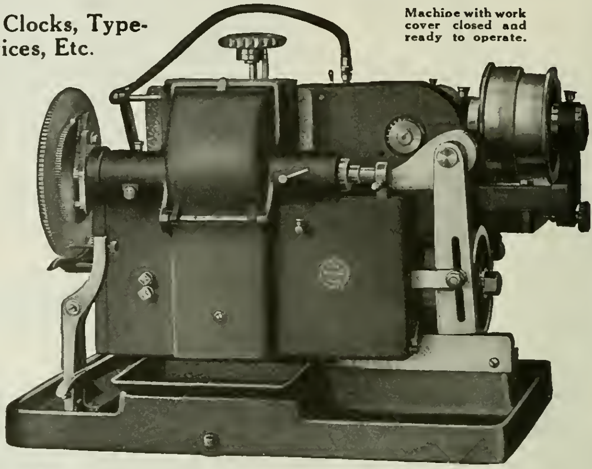
Waltham Pinion and Gear Cutting Machines

4" SPUR GEAR CUTTING MACHINES OF PRACTICAL DESIGN AND CAREFUL WORKMANSHIP

Of interest to Manufacturers of Clocks, Typewriters, Watches, Recording Devices, Etc.



Machine with work cover closed and ready to operate.

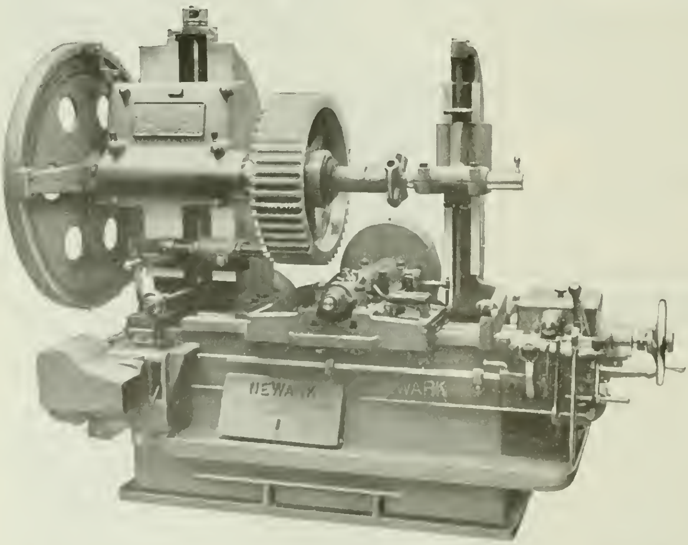
Machines so nearly automatic that they can be operated to good advantage in battery; that occupy only 18" by 28" of bench room, and provide four cutting speeds—300 and 375 R.P.M. for steel work, 1200 and 1500 R.P.M. for brass—and a standard 10" index with 120 divisions—8 to 120.

Though these machines are designed for production, they are so easily set up that they are equally profitable for jobbing; and individual geared pump, silent chain drive, plenty of ball bearings and other "quality" features insure uninterrupted satisfaction and low maintenance costs. Catalog on request.

Small Thread Millers, Gear Cutters and other small Automatic Machines

WALTHAM MACHINE WORKS, Newton St., Waltham, Mass.

Newark Spur Gear Cutting Machine



Newark Spur Gear Cutting Machines, for steady everyday run of gears.

Highest production per day. Lowest upkeep.

Nothing complicated to confuse the operator or to get out of order.

CLASSIFIED ADVERTISEMENTS
SITUATIONS, HELP WANTED, FOR SALE, ETC.

Advertisements in this section, 25 cents a line, seven words to a line—minimum, $1.50. The money should be sent with the order. Answers addressed to our care will be forwarded. Original letters of recommendation should not be enclosed to unknown correspondents.

HELP WANTED

SALESMAN WANTED.—Metropolitan district, New Jersey, Boston district to sell metal cutting tools and allied supplies direct to large consumers. F. A. BRADY, INC., 30 Church Street, New York.

MECHANICAL DRAFTSMEN having experience in the layout and design of high-speed and steam engine work or turbine work. Apply in writing, giving full information concerning salary, education and references. Box 558, care MACHINERY, 148 Lafayette St., New York.

SHOP AGENTS.—Represent us in your shop. Liberal commission on Reed Micrometers sold to your shopmates. Trustworthy tools at reasonable prices, backed by our iron-clad guarantee. Send for details, stating where employed. REED SMALL TOOL WORKS, 28 Cherry St., Worcester, Mass.

SIDE LINE SALESMEN to sell cast aluminum file and tool handles to manufacturers, machine shop hardware jobbers and dealers. You will find this a ready seller as well as staple. Write for prices and sample, stating clientele and territory. Generous commission. THE UNION ALUMINUM COMPANY, Orrville, O.

EMPLOYMENT SERVICE

A leading organization desiring to fill an important position, for obvious ethical and other reasons, cannot invite directly the candidacy of any particular man. Similarly, no well-connected man will exploit personally his own qualifications no matter how receptive he may be to overtures. The undersigned has been retained by a national clientele for many years, as a medium for negotiating preliminaries in such cases. Your permission to send booklet discussing this problem and describing the service, will in no degree obligate or compromise you. Strictly confidential. R. W. BIXBY, INC., 309 Lockwood Building, Buffalo, N. Y.

EMPLOYMENT SERVICE

EXECUTIVES.—Engineers and men of proven ability seeking positions find our service satisfactory. Our Mr. H. H. Harrison can confidentially negotiate for you suitable connections, as he has successfully done for thousands of others since 1909. Inquiries invited. THE NATIONAL BUSINESS BOURSE, INC., Confidential Negotiators, Association Bldg., Chicago.

PATENTS

PATENTS SECURED.—C. L. PARKER Ex-member Examining Corps, U. S. Patent Office. Instructions upon request. McGill Bldg., Washington, D. C.

IS YOUR WAY BETTER? Patent your improvements. We spare no effort to secure broadest protection. Skillful service. Prompt attention. Reasonable rates. Consult us. LAMB & CO., Solicitors of Patents, 1419 G Street, N. W., Washington, D. C.

PATENTS.—H. W. T. JENNER, patent attorney and mechanical expert, 622 F. St., Washington, D. C. Established 1883. I make an examination and report if a patent can be had, and the exact cost. Send for full information. Inventors assisted in developing ideas and inventions.

CONTRACT WORK

WANTED.—BY A MECHANICAL ENGINEER experienced in all lines connected with the machine building trade from patternmaking, moulding up to designing, to make acquaintance with a firm or party wanting some small machine or part manufactured in Canada. Product needing high-class workmanship preferred. Address Box 53, Bridgeport, Ontario, Canada.

CONTRACT WORK

GENERAL ENGINEERING & SUPPLY CO.—Consulting Engineers on special and automatic machinery. Design, improvement, construction, installation, import and export. Expert engineering service means a short-cut to perfect machinery. 160 Fifth Ave., Mohawk Bldg., New York.

WE WANT A GOOD SPECIALTY, or production work to manufacture, using a machine shop well equipped for medium work. We can also furnish castings and do wood or metal pattern work. Write or come and see us. SWEET & DOYLE FOUNDRY AND MACHINE COMPANY, Troy (Green Island), New York.

INVENTORS AND MANUFACTURERS.—Let us make that part or article for you. We have a light, modern factory centrally located, equipped with the most accurate and modern machinery. We make high-grade dies, tools and special machinery. Your correspondence invited. Write today. VICTOR ENGINEERING & MFG. CO., 2527 W. Chicago Ave., Chicago, Ill.

HEANY LABORATORIES, INC., ELECTRICAL, MECHANICAL AND PHYSICAL LABORATORIES.—We are prepared to take on a few developments and know that every manufacturer sooner or later has to lay aside some epoch-making improvement because he lacks the facilities for development. Our highly trained organization and completely equipped laboratories are now in a position to be of service to you. Lake Whitney, P. O. Box 530, New Haven, Connecticut.

FOR SALE

TRIANGLE TABLES for solving all parts of right triangles without formulas. A timesaver for draftsmen, toolmakers, patternmakers, etc. Two sets: In fractions, to 64ths or decimals to thousandths. Send 25c for sample sheet. S. C. CARPENTER, 62 So. Whitney St., Hartford, Conn.

IMPORTERS OF AMERICAN MACHINE TOOLS AND MACHINERY SUPPLIES

SOCIETE ANONYME DES ETABLISSEMENTS, FENWICK FRERES & CO.
8, Rue de Rocroy, Paris
AMERICAN MACHINERY AND TOOLS
Branches: Lyon, Lille and Nancy

GLAENZER & PERREAUD
18-20, Faubourg du Temple, Paris
IMPORTERS OF AMERICAN MACHINERY and Mechanical Supplies. Agent for the Niles-Bement-Pond Co., etc. Lieber's Code. A1 Code, A B C Code. Cable Address: Blakenilee, Paris.
New York Office: 33-39 West 34th Street.

ALFRED HERBERT, SOCIETE ANONYME
47, Boulevard de Magenta, Paris
Branch Offices at Lille and Lyons
IMPORTERS OF LABOR SAVING MACHINE TOOLS, SMALL TOOLS AND ACCESSORIES
Cable Address: Hexagon, Paris

ETABLISSEMENTS HORSTMANN
54-81-83 Rue St. Maur, Paris XI^e
IMPORTER OF AMERICAN MACHINERY, TOOLS AND STEELS. LARGE STOCK
New Buildings covering over 45,000 square feet under construction.
Telegrams: Acieroxo, Paris.

MAISON ADOLPHE JANSSENS
44, Rue de Prony, Paris
IMPORTERS OF AMERICAN MACHINE TOOLS AND SMALL TOOLS
Telegraphic Address: Outillage, Paris.
Branch Office in Brussels.

MOERCH & ROUMET, "L'OUTILLAGE MODERNE," Incorporated
120, Boulevard Richard Lenoir, Paris
Cable Address: "Roumoerch," Paris.
IMPORTERS OF AMERICAN MACHINE TOOLS AND MACHINERY SUPPLIES
Very large stock and Showrooms in Paris and Brussels.

FERNAND PERDRIZET
29 31, Rue de Chabrol, Paris, Xe
IMPORTER OF MACHINE TOOLS AND SUPPLIES
Telegraphic address: "Feperdrix, Paris."
Branch Office at Mulhouse:
No 37, rue des Trois Rois
(The first French firm established in 1900 in Alsace-Lorraine for importing Machine Tools.)

ETABLISSEMENTS SELSON
22 Boulevard Richard Lenoir, Paris
New York Office: 24 Stone St.
IMPORTERS OF MACHINE TOOLS AND SMALL TOOLS

STE AMERICAINE DE MACHINES-OUTILS 226 Rue Lafayette, Paris, Xe
DISTRIBUTORS OF AMERICAN MACHINE TOOLS CARRYING THE LARGEST STOCKS IN FRANCE
Agents throughout France
Large Demonstration Shops
117 Boulevard de la Villette, Paris, Xe
Cable Address: Samachinas, Paris

SOCIETE ANONYME "LA PRECISION MECANIQUE"
11, 13, 15 Rue Vergniaud, Paris
MEASURING TOOLS, COMPARATORS, INSIDE MICROMETERS, MICROMETERS, WHITWORTH S. I. THREAD GAGES AND PRECISION INSTRUMENTS
Telegrams Calibre, Paris.

JACQUES VIEYRA 24 Rue de Lubeck, Paris
IMPORTERS OF AMERICAN MACHINE TOOLS
Special Machinery

A most interesting general review of "The Machine Tool Trade in Japan" will be found on page 983 this number of MACHINERY. The information, which was furnished by Yamatake & Co., of Tokyo, Japan, will be of great value to the American manufacturer who is desirous of securing and holding Japanese trade. The company also offers some practical suggestions in the matter of handling and shipping, which, if followed, will go far towards avoiding the troubles that commonly beset the exporter.

FOR LOCATION OF ADVERTISEMENTS OF MANUFACTURERS LISTED IN THIS INDEX SEE ALPHABETICAL INDEX, PAGES 275-276

BRASIVE CLOTH AND PAPER
'arborundum Co., Niagara Falls, N. Y.

ACCUMULATORS, HYDRAULIC
'hambersburg Engineering Co., Chambersburg, Pa.
:lmes Eng. Works, Charles F., 222 North Morgan St., Chicago.
Iydraulic Press Mfg. Co., Mt. Gilead, Ohio.
Niles-Bement-Pond Co., 111 Broadway, New York.
Sellers & Co., Inc., Wm., Philadelphia.
Southwark Foundry & Machine Co., Philadelphia.
Watson-Stillman Co., 192 Fulton St., New York.

ACETYLENE APPARATUS
Air Reduction Sales Co., Inc., 342 Madison Ave., New York.

ACETYLENE, DISSOLVED
Air Reduction Sales Co., Inc., 342 Madison Ave., New York.
Prest-O-Lite Co., Inc., 30 E. 42d St., New York.

AIR HOISTS
See Hoists, Air.

ALLOYS, TUNGSTEN, URANIUM VANADIUM, MOLYBDENUM, ALUMINUM, ETC.
Baush Machine Tool Co., Springfield, Mass.
Haynes Stellite Co., 30 E. 42d St., New York.
Standard Alloys Co., Pittsburgh.
United Alloy Steel Corp., Canton, O.
Vanadium-Alloys Steel Co., Pittsburgh.

ANGLE PLATES, UNIVERSAL
Boston Scale & Mch. Co., Boston.

ANVILS
Columbian Hardware Co., Cleveland.
Fost Mfg. Co., Meadville, Pa.

ARBOR PRESSES
See Presses, Arbor.

ARBORS AND MANDRELS, EXPANDING
American Broach & Machine Co., Ann Arbor, Mich.
Eastern Tube & Tool Co., Brooklyn, N. Y.
McCrosky Tool Corp., Meadville, Pa.
Morse Twist Drill & Mch. Co., New Bedford, Mass.
Nicholson & Co., W. H., Wilkes-Barre, Pa.
Western Tool & Mfg. Co., Springfield, Ohio.
Whitman & Barnes Mfg. Co., Akron, Ohio.

ARBORS AND MANDRELS, SOLID
Alvord Reamer & Tool Co., Millersburg, Pa.
American Broach & Mch. Co., Ann Arbor, Mich.
Brown & Sharpe Mfg. Co., Providence, R. I.
Chapin-Skelton Corp., Syracuse, N. Y.
Cleveland Twist Drill Co., Cleveland.
Detroit Twist Drill Co., Detroit.
Greenfield Tap & Die Corp., Greenfield, Mass.
Morse Twist Drill & Mch. Co., New Bedford, Mass.
National Tool Co., Cleveland.
National Twist Drill & Tool Co., Detroit, Mich.
Nicholson & Co., W. H., Wilkes-Barre, Pa.
Pratt & Whitney Co., Hartford, Conn.
Rogers Works, Inc., J. M., Gloucester City, N. J.
Union Twist Drill Co., Athol, Mass.
Whitman & Barnes Mfg. Co., Akron, Ohio.

BABBITT
Ajax Metal Co., Philadelphia, Pa.
Besly & Co., Charles H., 120-B No. Clinton St., Chicago.
Doehler Die Casting Co., Brooklyn, N. Y.
Hoyt Metal Co., St. Louis, Mo.

BALANCING EQUIPMENT
Anderson Bros. Mfg. Co., Rockford, Illinois.
Divine Bros. Co., Utica, N. Y.
Norton Co., Worcester, Mass.
Rockford Tool Co., 2400 Eleventh St., Rockford, Ill.

BALLS, BRASS, STEEL, ETC.
Abbott Ball Co., Elmwood, Hartford, Conn.
Auburn Ball Bearing Co., 33 Elizabeth St., Rochester, N. Y.
Gwilliam Co., 253 West 58th St., New York.
Hoover Steel Ball Co., Ann Arbor, Mich.
Skayef Ball Bearing Co., 165 Broadway, New York.
S K F Industries, Inc., 165 Broadway, New York.

BARS, BORING
See Boring Bars.

BEARINGS, BABBITT
Franklin Die-Casting Corp., Syracuse, N. Y.
Johnson Bronze Co., New Castle, Pa.
Link-Belt Company, Chicago.
Royersford Fdry. & Machine Co., 54 North 5th St., Philadelphia.
Wood's Sons Co., T. B., Chambersburg, Pa.

BEARINGS, BALL
Auburn Ball Bearing Co., 33 Elizabeth St., Rochester, N. Y.
Ball & Roller Bearing Co., Danbury, Conn.
Bantam Ball Bearing Co., Bantam, Ct.
Bearings Co. of America, Lancaster, Pa.
Boston Gear Works, Norfolk Downs, Mass.
Cresson-Morris Co., Philadelphia.
Fafnir Bearing Co., New Britain, Ct.
Federal Bearings Co., Inc., Poughkeepsie, N. Y.
Gurney Ball Bearing Co., Jamestown, N. Y.
Gwilliam Co., 253 West 58th St., New York.
Hamilton Bearing & Mfg. Co., Philadelphia.
Langhaar Ball Bearing Co., Aurora, Ind.
Norma Co. of America, Long Island City, N. Y.
Schatz Mfg. Co., Poughkeepsie, N. Y.
Skayef Ball Bearing Co., 165 Broadway, New York.
S K F Industries, Inc., 165 Broadway, New York.
U. S. Ball Bearing Mfg. Co., 4563 Palmer St., Chicago.

BEARINGS, BRONZE
Ajax Metal Co., Philadelphia.
Besly & Co., Charles H., 120-B North Clinton St., Chicago.
Bunting Brass & Bronze Co., 748 Spencer St., St. Louis, Mo.
Johnson Bronze Co., New Castle, Pa.

BEARINGS, LINESHAFT
Royersford Foundry & Mch. Co., 54 North 5th St., Philadelphia.
Wood's Sons Co., T. B., Chambersburg, Pa.

BEARINGS, OILLESS
Arguto Oilless Bearing Co., 145 Berkley St., Wayne Junct'n, Philadelphia.

BEARINGS, ROLLER
Ball & Roller Bearing Co., Danbury, Conn.
Bantam Ball Bearing Co., Bantam, Ct.
Bock Bearing Co., Toledo, O.
Gwilliam Co., 253 West 58th St., New York.
Hamilton Bearing & Mfg. Co., Philadelphia.
Norma Co. of America, Long Island City, N. Y.
Royersford Foundry & Mch. Co., 54 North 5th St., Philadelphia.
Timken Roller Bearing Co., Canton, Ohio.

BEARINGS, SELF-OILING
Link-Belt Company, Chicago.
Skayef Ball Bearing Co., 165 Broadway, New York.
S K F Industries, Inc., 165 Broadway, New York.
Wood's Sons Co., T. B., Chambersburg, Pa.

BEARINGS, THRUST
Bearings Co. of America, Lancaster, Pa.
Bock Bearing Co., Toledo, O.
General Electric Co., Schenectady, N. Y.
Gwilliam Co., 253 West 58th St., New York.
Hamilton Bearing & Mfg. Co., Philadelphia.
Norma Co. of America, Long Island City, N. Y.
Skayef Ball Bearing Co., 165 Broadway, New York.
S K F Industries, Inc., 165 Broadway, New York.

BELT CEMENT
Chicago Rawhide Mfg. Co., 1301 Elston Ave., Chicago.
Schieren Co., Charles A., 73 Ferry St., New York.
Williams & Son, I. B., Dover, N. H.

BELT CLAMPS
Hoggson & Pettis Mfg. Co., New Haven, Conn.
Wood's Sons Co., T. B., Chambersburg, Pa.

BELT DRESSING
Chicago Rawhide Mfg. Co., 1301 Elston Ave., Chicago.
Dixon Crucible Co., Joseph, Jersey City, N. J.
Schieren Co., Charles A., 73 Ferry St., New York.

BELT FASTENERS, LEATHER
Chicago Rawhide Mfg. Co., 1301 Elston Ave., Chicago.
Schieren Co., Charles A., 73 Ferry St., New York.

BELT FASTENERS, METAL
Bristol Co., Waterbury, Conn.
Flexible Steel Lacing Co., 4622 Lexington St., Chicago.
Greene, Tweed & Co., 109 Duane St., New York.
Schieren Co., Charles A., 73 Ferry St., New York.

BELTING, LEATHER
Chicago Rawhide Mfg. Co., 1301 Elston Ave., Chicago.
Schieren Co., Charles A., 73 Ferry St., New York.
Williams & Sons, I. B., Dover, N. H.

BELTING, ROUND LEATHER
Chicago Rawhide Mfg. Co., 1301 Elston Ave., Chicago.
Schieren Co., Charles A., 73 Ferry St., New York.
Williams & Sons, I. B., Dover, N. H.

BELT LACING
Chicago Rawhide Mfg. Co., 1301 Elston Ave., Chicago.
Flexible Steel Lacing Co., 4622 Lexington St., Chicago.
Schieren Co., Charles A., 73 Ferry St., New York.
Williams & Sons, I. B., Dover, N. H.

BELT LACING, FLEXIBLE STEEL
Flexible Steel Lacing Co., 4622 Lexington St., Chicago.

BELT SHIFTERS
Haskins Co., R. G., 27 So. Desplaines St., Chicago.
Keuka Industries, Inc., Hammondsport, N. Y.
Wood's Sons Co., T. B., Chambersburg, Pa.

BENCH LEGS
Brown & Sharpe Mfg. Co., Providence, R. I.
Lupton's Sons Co., David, Philadelphia.
Standard Pressed Steel Co., Jenkintown, Pa.

BENDING MACHINES, ANGLE IRON
Buffalo Forge Co., Buffalo, N. Y.

BENDING MACHINES, HYDRAULIC
Hydraulic Press Mfg. Co., Mount Gilead, O.
Niles-Bement-Pond Co., 111 Broadway, New York.
Southwark Foundry & Machine Co., Philadelphia.
Watson-Stillman Co., 192 Fulton St., New York.
Williams, White & Co., Moline, Ill.

BENDING MACHINES, PIPE
Buffalo Forge Co., Buffalo, N. Y.
Niles-Bement-Pond Co., 111 Broadway, New York.
Pedrick Tool & Machine Co., 3639 N. Lawrence St., Philadelphia.
Sellers & Co., Inc., Wm., Philadelphia.
Southwark Foundry & Machine Co., Philadelphia.
Underwood Corp., H. B., Philadelphia.
Watson-Stillman Co., 192 Fulton St., New York.

BLOCKS, CHAIN
See Hoists, etc.

BLOWERS
American Gas Furnace Co., Elizabeth, N. J.
Buffalo Forge Co., Buffalo, N. Y.
Canedy-Otto Mfg. Co., Chicago Heights, Ill.
Chicago Flexible Shaft Co., 1154 So. Central Ave., Chicago.
General Electric Co., Schenectady, N. Y.
Westinghouse Electric & Mfg. Co., E. Pittsburgh, Pa.

BLOWERS, POSITIVE
Chicago Flexible Shaft Co., 1154 So. Central Ave., Chicago.
Leiman Bros., 81 Walker St., New York.

BLUEPRINT DYING MACHINES
Dietzgen Co., Eugene, 166 W. Monroe St., Chicago.
Keuffel & Esser Co., Hoboken, N. J.
Paragon Machine Co., Rochester, N. Y.

BLUEPRINT FILING CABINETS
See Cabinets, Filing.

BLUEPRINT MACHINES
Dietzgen Co., Eugene, 166 W. Monroe St., Chicago.
Keuffel & Esser Co., Hoboken, N. J.
Paragon Machine Co., Rochester, N. Y.

BLUEPRINT PAPER
Dietzgen Co., Eugene, 166 W. Monroe St., Chicago.
Keuffel & Esser Co., Hoboken, N. J.
Paragon Machine Co., Rochester, N. Y.

BOILER TUBES
Chase Metal Works, Waterbury, Conn.
National Tube Co., Pittsburgh, Pa.
Ryerson & Son, Joseph T., 2558 W. 16th St., Chicago.

BOLT AND NUT MACHINERY
Acme Machinery Co., Cleveland.
Ajax Mfg. Co., Cleveland.
Foote-Burt Co., Cleveland.
Landis Machine Co., Inc., Waynesboro, Pa.
National Acme Co., Cleveland.
National Machinery Co., Tiffin, O.

BOLTS AND NUTS
National Acme Co., Cleveland.
Ryerson & Son, Joseph T., 2558 W. 16th St., Chicago.

BOOKS, TECHNICAL
Industrial Press, 148 Lafayette St., New York.

BOOSTERS
Westinghouse Electric & Mfg. Co., E. Pittsburgh, Pa.

BORING AND DRILLING MACHINES, VERTICAL
Baker Bros., Toledo, O.
Barnes Drill Co., Inc., 814 Chestnut St., Rockford, Ill.
Colburn Machine Tool Co., Cleveland.
Foote-Burt Co., Cleveland.
Gisholt Machine Co., 9 So. Baldwin St., Madison, Wis.
Moline Tool Co., Moline, Ill.
Niles-Bement-Pond Co., 111 Broadway, New York.
Sellers & Co., Inc., Wm., Philadelphia.

BORING AND TURNING MILLS, VERTICAL
Betts Machine Co., Rochester, N. Y.
Cincinnati Planer Co., Cincinnati.
Colburn Machine Tool Co., Cleveland.
Gisholt Machine Co., 9 South Baldwin St., Madison, Wis.
Niles-Bement-Pond Co., 111 Broadway, New York.
Ryerson & Son, Joseph T., 2558 W. 16th St., Chicago.
Sellers & Co., Inc., Wm., Philadelphia.

BORING BARS
American Hollow Boring Co., Erie, Pa.
American Machine & Fdry. Co., 5520 Second Ave., Brooklyn, N. Y.
Armstrong Bros. Tool Co., 313 No. Francisco Ave., Chicago.
Beaman & Smith Co., Providence, R. I.
Davis Boring Tool Co., St. Louis, Mo.
Gisholt Machine Co., 9 So. Baldwin St., Madison, Wis.
Hannifin Mfg. Co., Kolmar Ave. and Lexington St., Chicago.
Lovejoy Tool Co., Inc., Springfield, Vt.
Madison Mfg. Co., Muskegon, Mich.
Marvin & Casler Co., Canastota, N. Y.
Pedrick Tool & Machine Co., 3639 N. Lawrence St., Philadelphia.
Ryerson & Son, Joseph T., 2558 W. 16th St., Chicago.
Chapin-Skelton Corp., Syracuse, N. Y.
Underwood Corp., H. B., Philadelphia.
Williams & Co., J. H., 61 Richards St., Brooklyn, N. Y.

BORING, DRILLING AND MILLING MACHINES, HORIZONTAL
Barnes Co., W. F. & John, 231 Ruby St., Brooklyn, N. Y.
Beaman & Smith Co., Providence, R. I.
Betts Mch. Co., Rochester, N. Y.
Gisholt Machine Co., 9 So. Baldwin St., Madison, Wis.
Landis Tool Co., Waynesboro, Pa.
Lucas Mch. Tool Co., Cleveland.
Milwaukee Electric Crane & Mfg. Co., Milwaukee, Wis.
Newton Machine Tool Works, Inc., Philadelphia.
Niles-Bement-Pond Co., 111 Broadway New York.
Pedrick Tool & Mch. Co., 3639 No. Lawrence St., Philadelphia.

Rockford Drilling Machine Co., Rockford, Ill.
Sellers & Co., Inc., Wm., Philadelphia.

BORING HEADS, OFFSET

Marvin & Casler Co., Canastota, N. Y.
Porter-Cable Machine Co., Syracuse, N. Y.
Rickert Shafer Co., Erie, Pa.

BORING TOOLS

American Hollow Boring Co., Erie, Pa.
Armstrong Bros. Tool Co., 313 North Francisco Ave., Chicago.
Davis Boring Tool Co., Inc., St. Louis.
Hannifin Mfg. Co., Kolmar Ave. and Lexington St., Chicago.
Lovejoy Tool Co., Inc., Springfield, Vt.
Morse Twist Drill & Mch. Co., New Bedford, Mass.
O. K. Tool Holder Co., Shelton, Ct.
Western Tool & Mfg. Co., Springfield, Ohio.
Williams & Co., J. H., 61 Richards St., Brooklyn, N. Y.

BOXES, CARBONIZING

Farrell-Cheek Steel Fdry. Co., Sandusky, O.

BOXES, SHOP, STEEL

Brown & Sharpe Mfg. Co., Providence, R. I.

BRAKES, BENDING

Loy & Nawrath, 30 Church St., New York.

BRASS AND COPPER RODS, SHEETS, TUBES

Bridgeport Brass Co., Bridgeport, Ct.
Chase Metal Works, Waterbury, Conn.

BRAZING EQUIPMENT

Chicago Flexible Shaft Co., 1154 So. Central Ave., Chicago.

BROACHES

American Broach & Machine Co., Ann Arbor, Mich.
Hurlbut-Rogers Broach Co., Hudson, Mass.
Lapointe Co., J. N., New London, Ct.
Lapointe Machine Tool Co., Hudson, Mass.

BROACH GRINDING MACHINES

Lapointe Co., J. N., New London, Ct.

BROACHING MACHINES

American Broach & Machine Co., Ann Arbor, Mich.
Lapointe Co., J. N., New London, Ct.
Lapointe Machine Tool Co., Hudson, Mass.
V & O Press Co., Glendale, Long Island, N. Y.

BROACHING PRESS, HAND

American Broach & Machine Co., Ann Arbor, Mich.

BRONZE

Ajax Metal Co., Philadelphia, Pa.
Bunting Brass & Bronze Co., 748 Spencer St., Toledo, O.
Chase Metal Works, Waterbury, Conn.
Johnson Bronze Co., New Castle, Pa.

BRONZE WIRE, RODS AND SHEETS

Bridgeport Brass Co., Bridgeport, Conn.
Chase Metal Works, Waterbury, Conn.

BUFFERS

Blount Co., J. C., Everett, Mass.
Bridgeport Safety Emery Wheel Co., Inc., Bridgeport, Conn.
Builders Iron Foundry, Providence, R. I.
Canedy-Otto Mfg. Co., Chicago Heights, Ill.
Chicago Flexible Shaft Co., 1154 So. Central Ave., Chicago.
Dillon Electric Co., Canton, O.
Divine Bros. Co., Utica, N. Y.
Forbes & Myers, 178 Union St., Worcester, Mass.
Neil & Smith Electric Tool Co., Cincinnati.
Stow Mfg. Co., Binghamton, N. Y.
Valley Electric Co., 3163 So. Kingshighway, St. Louis, Mo.

BUFFING MACHINES, AUTOMATIC

Automatic Buffing Machine Co., Inc., Buffalo, N. Y.

BULLDOZERS

Ajax Mfg. Co., Cleveland.
Bliss Co., E. W., Brooklyn, N. Y.
National Machinery Co., Tiffin, O.
Ryerson & Son, Joseph T., 2558 West 16th St., Chicago.
Southwark Foundry & Machine Co., Philadelphia.
Watson-Stillman Co., 192 Fulton St., New York.
Williams, White & Co., Moline, Ill.

BURNERS, GAS AND OIL

Chicago Flexible Shaft Co., 1154 So. Central Ave., Chicago.
Surface Combustion Co., 362 Gerard Ave., New York.

BURNISHING MACHINERY

Abbott Ball Co., Elmwood, Hartford, Conn.
Baird Machine Co., Bridgeport, Conn.
Globe Mch. & Stamping Co., Cleveland, O.

BURRING MACHINES, FORGING

Ajax Mfg. Co., Cleveland, O.

BUSHINGS, BRASS, BRONZE, ETC.

Brown Engineering Co., 133 No. 3rd St., Reading, Pa.
Bunting Brass & Bronze Co., 748 Spencer St., Toledo, O.
Wilmington Fibre Specialty Co., Wilmington, Del.

CABINETS, FILING

Dietzgen Co., Eugene, 166 W. Monroe St., Chicago.
Economy Drawing Table & Mfg. Co., Adrian, Mich.
Keuffel & Esser Co., Hoboken, N. J.
Paragon Machine Co., Rochester, N. Y.

CABINETS, TOOL

Armstrong Bros. Tool Co., 313 North Francisco Ave., Chicago, Ill.
Gerstner & Sons, H., Dayton, O.
Lupton's Sons Co., David, Philadelphia, Pa.
Morse Twist Drill & Mch. Co., New Bedford, Mass.
Whitman & Barnes Mfg. Co., Akron, Ohio.

CALCIUM CARBIDE

Air Reduction Sales Co., Inc., 342 Madison Ave., N. Y.

CALIPER GAGES

Williams & Co., J. H., 61 Richards St., Brooklyn, N. Y.

CALIPERS, BOW

Brown & Sharpe Mfg. Co., Providence, R. I.
Goodell-Pratt Co., Greenfield, Mass.
Starrett Co., L. S., Athol, Mass.

CALIPERS, MICROMETER

Almond Mfg. Co., T. R., Ashburnham, Mass.
Brown & Sharpe Mfg. Co., Providence, R. I.
Goodell-Pratt Co., Greenfield, Mass.
Slocomb Co., J. T., Providence, R. I.
Starrett Co., L. S., Athol, Mass.

CAMS

American Machine & Foundry Co., 5520 Second Ave., Brooklyn, N. Y.
Garvin Machine Co., Spring and Varick Sts., New York.
Rowbottom Mch. Co., Waterbury, Ct.

CASE-HARDENING

Meisel Press Mfg. Co., 948 Dorchester Ave., Boston 25, Mass.
Pittsburgh Gear & Mch. Co., 2700 Smallman St., Pittsburgh.
Williams & Co., J. H., 61 Richards St., Brooklyn, N. Y.

CASE-HARDENING COMPOUND

Kasenit Co., 30 South William St., New York.

CASE-HARDENING FURNACES

See Furnaces, Case-Hardening.

CASTINGS, BRASS, BRONZE AND ALUMINUM

Ajax Metal Co., Philadelphia.
Machinery Co. of America, Big Rapids, Mich.

CASTINGS, DIE OR DIE MOLDED

Doehler Die-Casting Co., Brooklyn, N. Y.
Franklin Die Casting Corp., Syracuse, N. Y.
Mt. Vernon Die-Casting Corp., Mt. Vernon, N. Y.
Republic Die Casting Co., 138 Mott St., New York.
Superior Die-Casting Co., Cleveland.
Veeder Mfg. Co., 39 Sargeant St., Hartford, Conn.

CASTINGS, DIE OR DIE MOLDED ALUMINUM

Doehler Die-Casting Co., Brooklyn, N. Y.
Franklin Die-Casting Corp., Syracuse, N. Y.
Mt. Vernon Die-Casting Corp., Mt. Vernon, N. Y.
Republic Die Casting Co., 138 Mott St., New York.
Superior Die-Casting Co., Cleveland.

CASTINGS, GRAY IRON

Brown & Sharpe Mfg. Co., Providence, R. I.
Cresson-Morris Co., Philadelphia.
Machinery Co. of America, Big Rapids, Mich.
Sinclair Engine & Fdry. Co., Inc., New Orleans, La.
Sweet & Doyle Foundry & Machine Co., Troy, N. Y.
Whitcomb-Blaisdell Machine Tool Co., Worcester, Mass.

CASTINGS, MALLEABLE

Link-Belt Company, Chicago.

CASTINGS, STEEL

Cresson-Morris Co., Philadelphia.
Farrell-Cheek Steel Foundry Co., Sandusky, O.

CEMENT, DISC GRINDING WHEEL

Badger Tool Co., Beloit, Wis.
Gardner Machine Co., Beloit, Wis.

CENTERING MACHINES

Hanson-Whitney Machine Co., Hartford, Conn.
Hendey Mch. Co., Torrington, Conn.
Newton Mch. Tool Works, Inc., Philadelphia, Pa.
Niles-Bement-Pond Co., 111 Broadway New York.
Porter Cable Machine Co., Syracuse, N. Y.
Pratt & Whitney Co., Hartford, Conn.
Standard Engineering Works, Pawtucket, R. I.
Whiton Mch. Co., D. E., New London, Conn.

CENTERS, PLANER AND MILLER

Cincinnati Planer Co., Cincinnati.
Morse Twist Drill & Mch. Co., New Bedford, Mass.

CHAIN BLOCKS

See Hoists, Chains, etc.

CHAIN, CABLE FOR COUNTERWEIGHTS, ETC.

Morton, Thomas, 245 Centre St., New York.
Smith & Egge Mfg. Co., Bridgeport, Conn.

CHAINS, POWER TRANSMISSION

Baldwin Chain & Mfg. Co., Worcester, Mass.
Boston Gear Works, Norfolk Downs, Mass.
Diamond Chain & Mfg. Co., Indianapolis, Ind.
Duckworth Chain & Mfg. Co., Springfield, Mass.
Link-Belt Company, Chicago.
Morse Chain Co., Ithaca, N. Y.
Morton, Thomas, 245 Centre St., New York.
Whitney Mfg. Co., Hartford, Conn.

CHECKS, TIME, TOOL AND PAY

Matthews & Co., Jas. H., Pittsburgh.
Noble & Westbrook Mfg. Co., Hartford, Conn.
Pannier Bros. Stamp Co., Pittsburgh.
Schwerdtle Stamp Co., Bridgeport, Ct.

CHISEL BLANKS

Hunter Saw & Mch. Co., Pittsburgh.

CHUCKING MACHINES, AUTOMATIC

Gisholt Machine Co., 9 South Baldwin St., Madison, Wis.
Jones & Lamson Mch. Co., Springfield, Vt.
McDonough Mfg. Co., Eau Claire, Wis.
Potter & Johnston Machine Co., Pawtucket, R. I.

CHUCKING MACHINES, MULTIPLE SPINDLE, AUTOMATIC

McDonough Mfg. Co., Eau Claire, Wis.

CHUCKING MACHINES, SEMI-AUTOMATIC

Brown & Sharpe Mfg. Co., Providence, R. I.
Gisholt Machine Co., 9 South Baldwin St., Madison, Wis.
Jones & Lamson Mch. Co., Springfield, Vt.
National Acme Co., Cleveland.

CHUCKS, AIR-OPERATED

Bardons & Oliver, Cleveland.
Frontier Chuck & Tool Co., Buffalo, N. Y.
Garvin Machine Co., Spring and Varick Sts., New York.
Hannifin Mfg. Co., Kolmar Ave. and Lexington St., Chicago.
Nelson-Blanck Mfg. Co., Detroit, Mich.
S-P Mfg. Co., Cleveland.

CHUCKS, COLLET OR SPLIT

Ames Co., B. C., Waltham, Mass.
Hardinge Bros., Inc., Bertean and Ravenswood Aves., Chicago.
Ney Co., J. M., Hartford, Conn.
Rivett Lathe & Grinder Co., Brighton, Boston.
Standard Engineering Works, Pawtucket, R. I.
Stark Tool Co., Waltham, Mass.

CHUCKS, DRILL

Almond Mfg. Co., T. R., Ashburnham, Mass.
Beaman & Smith Co., Providence, R. I.
Cleveland Twist Drill Co., Cleveland.
Cushman Chuck Co., Hartford, Conn.
Detroit Twist Drill Co., Detroit.
Eastern Tube & Tool Co., Inc., Brooklyn, N. Y.
Goodell-Pratt Co., Greenfield, Mass.
Horton & Son Co., E., Windsor Locks, Conn.
Jacobs Mfg. Co., Hartford, Conn.
Johansson, Inc., C. E., Poughkeepsie, N. Y.
Marvin & Casler Co., Canastota, N. Y.
McCrosky Tool Corp., Meadville, Pa.
Modern Tool Co., 2nd and State Sts., Erie, Pa.

Morse Twist Drill & Mch. Co., New Bedford, Mass.
Narragansett Machine Co., Providence, R. I.
National Twist Drill & Tool Co., Detroit.
Scully-Jones & Co., 2013 W. 13th St., Chicago.
Skinner Chuck Co., New Britain, Ct.
Titan Tool Co., Erie, Pa.
Trump Bros. Machine Co., Wilmington, Del.
Union Mfg. Co., New Britain, Conn.
Westcott Chuck Co., Oneida, N. Y.
Watts Bros. Tool Works, Turtle Creek, Pa.
Whiton Machine Co., D. E., New London, Conn.

CHUCKS, ECCENTRIC BORING

Marvin & Casler Co., Canastota, N. Y.

CHUCKS, FULL FLOATING

Watts Bros. Tool Works, Turtle Creek, Pa.

CHUCKS, LATHE, ETC.

Almond Mfg. Co., T. R., Ashburnham, Mass.
Cushman Chuck Co., Hartford, Conn.
Foster Machine Co., Elkhart, Ind.
Gisholt Machine Co., 9 South Baldwin St., Madison, Wis.
Hardinge Bros., Inc., Berteau and Ravenswood Aves., Chicago.
Hoggson & Pettis Mfg. Co., New Haven, Conn.
Horton & Son Co., E., Windsor Locks, Conn.
McCrosky Tool Corp., Meadville, Pa.
Rivett Lathe & Grinder Co., Brighton District, Boston.
Ryerson & Son, Joseph T., 2558 West 16th St., Chicago.
Sinclair Engine & Fdry. Co., Inc., New Orleans, La.
Skinner Chuck Co., New Britain, Ct.
Union Mfg. Co., New Britain, Conn.
Westcott Chuck Co., Oneida, N. Y.
Whiton Mch. Co., D. E., New London, Conn.

CHUCKS, MAGNETIC

Heald Mch. Co., 16 New Bond St., Worcester, Mass.
Walker Co., Inc., O. S., Worcester, Mass.

CHUCKS, PLANER

Cincinnati Planer Co., Cincinnati, O.
Cushman Chuck Co., Hartford, Conn.
Hoggson & Pettis Mfg. Co., New Haven, Conn.
Horton & Son Co., E., Windsor Locks, Conn.
Skinner Chuck Co., New Britain, Ct.
Union Mfg. Co., New Britain, Conn.

CHUCKS, TAPPING

Beaman & Smith Co., Providence, R. I.
Errington Mechanical Laboratory, Broadway and John St., New York.

FACTS ABOUT PRODUCTION
ON A LARGE TRACTOR MOTOR
Machine has power and rigidity at high speeds
Proper fixtures hold and support the work
Properly constructed cutter bodies hold and support the blades
Result: Stellite blades roughing and finishing remove metal rapidly and accurately at the lowest possible cost
STELLITE BLADES IN PRODUCTION TOOL COMPANY CUTTERS PERIPHERY SPEED 117 FEET PER MINUTE
TABLE TRAVEL 13 INCHES PER MINUTE
ACCUMULATIVE TOOL & LABOR COSTS SAVING OF MAN & MACHINE HOURS AND INCREASED RETURNS ON INVESTMENT
SHOWN BY MOTION STUDY PLAN STELLITE OTHER TOOLS
Cylinder heads per grind 173 30
Cuts per grind 519 90
Grinds to life 1 set cutters 128 128
Cuts to 1 set of blades 66432 11520
Hours required for 66432 cuts 2214 2768
Grinds required for 66432 cuts 128 738
One set of blades $82.26 $34.91
Blades to mill 66432 cuts 82.26 201.29
Fitting extra blades 0.00 59.62
Grinding to mill 66432 cuts 44.80 258.30
Total tool cost 22144 castings 127.06 519.21
Total tool cost per casting .0057 .0234
STELLITE SAVINGS
Labor and machine cost @ $1.00 per hour $554.00
Tool cost 392.15
TOTAL SAVINGS $946.15

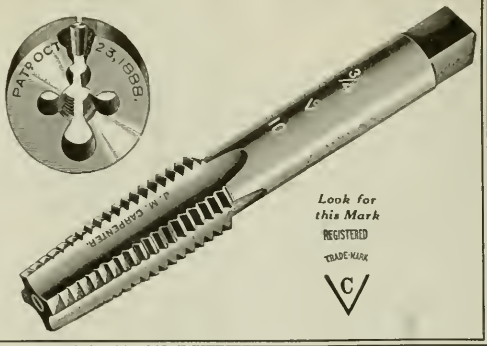
CARPENTER

For Fifty-two Years

Carpenter Thread Cutting Tools have given profitable service on all classes of work. Carefully designed, correctly made—always meeting the increasing demands of the metal working standards of the last half century—they have made the Carpenter Trade Mark a sure sign of tool satisfaction.

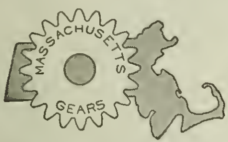
Taps, Dies, Die Stocks, Screw Plate Dies, Tap Wrenches; send for the catalog.

The J. M. Carpenter Tap & Die Co.
PAWTUCKET RHODE ISLAND



Specialized Production of Small and Medium Sized Gears

High quality gears, good deliveries, moderate prices. Try them.



ALL TYPES: Spur, Mitres, Bevels, Spirals, Worms, Worm Gears, Sprockets.

ANY MATERIAL: Steel, Cast Iron, Brass, Bronze, Fibre, Bakelite, Rawhide.

DRILLS, REAMERS, TAPS, CUTTERS

ALVORD REAMER & TOOL CO., Millersburg, Pa., U.S.A.

The "Ball" Expansion Inserted Blade Hand Reamer

Bodies of reamers are hardened all over. Furnished with either Carbon or High Speed Steel Blades. Both kinds carried in stock. Uniform expansion of the blades. The expansion of the blades does not throw the body of the reamer out of true. Large range of expansion. Made for the best class of hand reaming. Some of the leading automobile companies use these reamers. Made in sizes from $\frac{3}{4}''$ to $2\frac{1}{2}''$. Descriptive circular sent upon request.

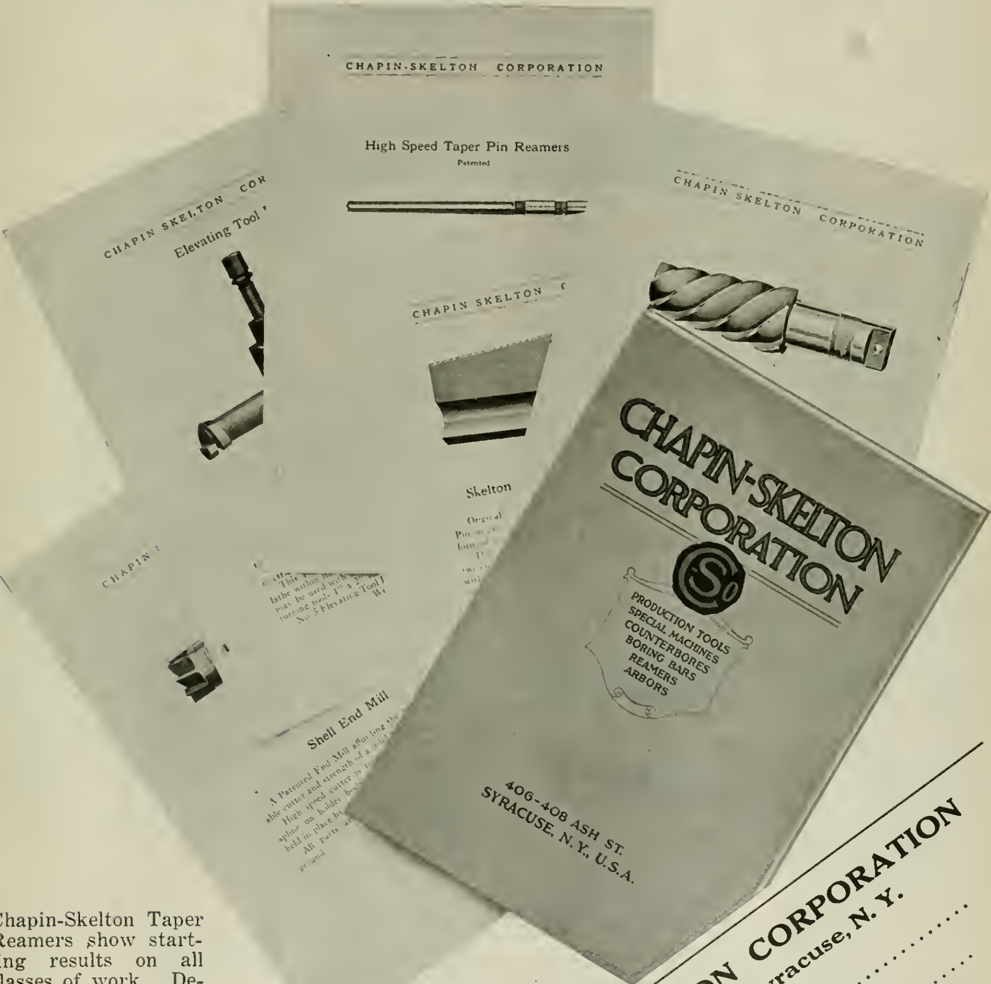
CHAPIN-SKELTON

A New Catalogue of

Production Tools



Chapin-Skelton Taper Reamers show startling results on all classes of work. Developed in conjunction with the Automobile Gear Industry they are thoroughly modern tools that *get production* on the most difficult operations.

Learn more about them—clip the coupon for your copy of our new catalog.

MILLING MACHINES, HORIZONTAL, UNIVERSAL

Brown & Sharpe Mfg. Co., Providence, R. I.
Cincinnati Milling Machine Co., Oakley, Cincinnati.
Hendey Mch. Co. Torrington, Conn.
Kearney & Trecker Corp., Milwaukee, Wis.
Kempsmith Mfg. Co., Milwaukee, Wis.
LeBlond Mch. Tool Co., R. K., Cincinnati.
McCrosky Tool Corp., Meadville, Pa.
Niles-Bement-Pond Co., 111 Broadway, New York
Oesterlein Machine Co., Cincinnati.
Rockford Milling Machine Co., Rockford, Ill.
Rowbottom Mch. Co., Waterbury, Ct.
Ryerson & Son, Joseph T., 2558 W. 16th St., Chicago.
Van Norman Mch. Tool Co., Springfield, Mass.

MILLING MACHINES, LINCOLN TYPE

Beaman & Smith Co., Providence, R. I.
Becker Milling Mch. Co., Worcester, Mass.
Brown & Sharpe Mfg. Co., Providence, R. I.
Garvin Machine Co., Spring and Varick Sts., New York.
Hendey Mch. Co., Torrington, Conn.
Kempsmith Mfg. Co., Milwaukee, Wis.
Pratt & Whitney Co., Hartford, Conn.
Reynolds Mch. Co., Massillon, O.
Van Norman Mch. Tool Co., Springfield, Mass.

MILLING MACHINES, MULTIPLE SPINDLE

Automatic Mch. Co., Bridgeport, Ct.
Beaman & Smith Co., Providence, R. I.
Ingersoll Milling Machine Co., Rockford, Ill.
Newton Machine Tool Works, Inc., Philadelphia.
Niles-Bement-Pond Co., 111 Broadway, New York.

MILLING MACHINES, PORTABLE

Ingersoll Milling Machine Co., Rockford, Ill.
Newton Machine Tool Works, Inc., Philadelphia.
Pedrick Tool & Machine Co., 3639 N. Lawrence St., Philadelphia.
Underwood Corp., H. B., Philadelphia.

MILLING MACHINE, SPLINE

Pratt & Whitney Co., Hartford, Conn.
Standard Engineering Works, Pawtucket, R. I.

MILLING MACHINES, VERTICAL

Beaman & Smith Co., Providence, R. I.
Becker Milling Mch. Co., Worcester, Mass.
Brown & Sharpe Mfg. Co., Providence, R. I.
Cincinnati Milling Mch. Co., Oakley, Cincinnati.
Garvin Machine Co., Spring and Varick Sts., New York.
Ingersoll Milling Machine Co., Rockford, Ill.
Kearney & Trecker Corp., Milwaukee, Wis.
Knight Mchy. Co., W. B., St. Louis.
LeBlond Mch. Tool Co., R. K., Cincinnati.
Newton Mch. Tool Works, Inc., Philadelphia.
Niles-Bement-Pond Co., 111 Broadway, New York.
Ryerson & Son, Joseph T., 2558 W. 16th St., Chicago.
Taylor & Fenn Co., Hartford, Conn.
Van Norman Mch. Tool Co., Springfield, Mass.

MILLING TOOLS, HOLLOW, ADJUSTABLE

Geometric Tool Co., New Haven, Ct.
Rogers Works, Inc., J. M., Gloucester City, N. J.

MODEL AND EXPERIMENTAL WORK

See Special Machinery and Tools.

MOLDING MACHINES

Adams Co., Dubuque, Iowa
Hanna Engineering Works, 1763 Elston Ave., Chicago.

MOTORS, ELECTRIC

Dillon Electric Co., Canton, O.
General Electric Co., Schenectady, N. Y.
Marathon Electric & Mfg. Co., Wausau, Wis.
Reliance Electric & Eng. Co., 1056 Ivanhoe Road, Chicago.
Valley Electric Co., 3163 So. Kingshighway, St. Louis, Mo.

Schwerdtle Stamp Co., Bridgeport, Conn.

NIPPLE THREADING MACHINERY

Bignall & Keeler Machine Works, Edwardsville, Ill.
Landis Machine Co., Inc., Waynesboro, Pa.
Merrell Mfg. Co., 15 Curtis St., Toledo, O.
Murchey Mch. & Tool Co., 34 Porter St., Detroit.
Saunders' Sons, Inc., D., Yonkers, N. Y.

NUTS, CASTELLATED

National Acme Co., Cleveland.

NUT TAPPERS

See Bolt and Nut Machinery

ODOMETERS

Veeder Mfg. Co., 39 Sargeant St., Hartford, Conn.

OIL CUPS

Besly & Co., Charles H., 120-B No. Clinton St., Chicago.
Bowen Products Corp., Auburn, N. Y.
Gits Bros. Mfg. Co., 1901 South Kilbourne Ave., Chicago.
Tucker, W. M. & C. F., Hartford, Conn.

OILERS

Gem Mfg. Co., Pittsburgh, Pa.
Hanna Engineering Works, 1763 Elston Ave., Chicago.

OILERS, LOOSE PULLEY

Brown Engineering Co., 133 No. 3rd St., Reading, Pa.

OIL EXTRACTORS

Tolhurst Mch. Works, Troy, N. Y.

OIL GROOVING TOOLS

Hanson-Whitney Machine Co., Hartford, Conn.

OIL HOLE COVERS

Bowen Products Corp., Auburn, N. Y.
Gits Bros. Mfg. Co., 1901 South Kilbourne Ave., Chicago.
Tucker, W. M. & C. F., Hartford, Conn.

OILS, LUBRICATING

Besly & Co., Charles H., 120-B North Clinton St., Chicago.
Sun Company, Philadelphia.
Texas Co., 17 Battery Pl., New York.

OILS, QUENCHING AND TEMPERING

Sun Company, Philadelphia.
Texas Co., 17 Battery Pl., New York.

OILS, SOLUBLE

See Compound, Cutting, Grinding, etc.

OVENS, BAKING

American Gas Furnace Co., Elizabeth, N. J.
General Electric Co., Schenectady, N. Y.

OVENS, TEMPERING

General Electric Co., Schenectady, N. Y.

OXY-ACETYLENE APPARATUS

See Welding and cutting, Oxy-Acetylene Equipment.

OXYGEN

Air Reduction Sales Co., Inc., 342 Madison Ave., New York.
Linde Air Products Co., 30 E. 42nd St., New York.

PACKING, LEATHER

Chicago Rawhide Mfg. Co., 1301 Elston Ave., Chicago.

PARALLELS

Walker Co., Inc., O. S., Worcester, Mass.

PATENTS

Parker, C. L., Washington, D. C.

PATTERN SHOP MACHINERY

Crescent Machine Co., 56 Main St., Leetonia, O.

PATTERNS, METAL

Grant Mfg. & Machine Co., N. W. Station, Bridgeport, Conn.
Mummert-Dixon Co., Hanover, Pa.
S P Mfg. Co., Cleveland.
Sweet & Doyle Fdry. & Mch. Co., Troy, N. Y.

PATTERNS, WOOD

S P Mfg. Co., Cleveland.
Sweet & Doyle Fdry. & Mch. Co., Troy, N. Y.
V & O Press Co., Glendale, Long Island, N. Y.

PENCILS, DRAWING

American Lead Pencil Co., 230 Fifth Ave., New York.
Dietzgen Co., Eugene, 166 W. Monroe St., Chicago.
Dixon Crucible Co., Jos., Jersey City N. J.

PHOSPHOR BRONZE

See Bronze.

PHOTOGRAPHIC COPYING MACHINES

Photostat Corp., Rochester, N. Y.

PHOTOSTATS

Photostat Corp., Rochester, N. Y.

PINIONS, FORGED

See Gears, Forged.

PIPE, STEEL

Mohegan Tube Co., 308 Scott Ave., Brooklyn, N. Y.
National Tube Co., Pittsburgh.

PIPE BENDING TOOLS

Pedrick Tool & Machine Co., 3639 N. Lawrence St., Philadelphia.
Underwood Corp., H. B., Philadelphia.

PIPE CUTTING AND THREADING MACHINES

Armstrong Mfg. Co., Bridgeport, Conn.
Bignall & Keeler Mch. Works, Edwardsville Ill.
Curtis & Curtis Co., 324 Garden St., Bridgeport, Conn.
Foote-Burt Co., Cleveland.
Greenfield Tap & Die Corp., Greenfield, Mass.
Harrington, Son & Co., Inc., Edwin, Philadelphia.
Hart Mfg. Co., East 20th and Marion Ave., Cleveland.
Landis Machine Co., Inc., Waynesboro, Pa.
Merrell Mfg. Co., 15 Curtis St., Toledo, O.
Murchey Mch. & Tool Co., 34 Porter St., Detroit.
Saunders' Sons, Inc., D., Yonkers, N. Y.
Victor Tool Co., Madison & W. M. R. R., Waynesboro, Pa.

PLANER ATTACHMENTS

Cincinnati Planer Co., Cincinnati.
Gray Co., G. A., Cincinnati.
Hanson-Whitney Machine Co., Hartford, Conn.
Reed-Prentice Co., Worcester, Mass.

PLANERS

American Tool Works Co., Cincinnati.
Betts Machine Co., Rochester, N. Y.
Cincinnati Planer Co., Cincinnati.
Cleveland Planer Co., 3125 Superior Ave., Cleveland.
Gray Co., G. A., Cincinnati.
Hamilton Mch. Tool Co., Hamilton, O.
Liberty Mch. Tool Co., Hamilton, O.
Morton Mfg. Co., Muskegon Heights, Mich.
Niles-Bement-Pond Co., 111 Broadway, New York.
Ohio Machine Tool Co., Kenton, O.
Rockford Mch. Tool Co., Rockford, Ill.
Ryerson & Son, Joseph T., 2558 W. 16th St., Chicago.
Sellers & Co., Inc., Wm., Philadelphia.
Whitcomb-Blaisdell Machine Tool Co., Worcester, Mass.
Woodward & Powell Planer Co., Worcester, Mass.

PLANERS, CRANK

Cincinnati Shaper Co., Cincinnati, O.
Newton Mch. Tool Works, Inc., Philadelphia.

PLANERS, OPEN-SIDE

Automatic Mch. Co., Bridgeport, Ct.
Cleveland Planer Co., 3152 Superior Ave., Cleveland.
Liberty Mch. Tool Co., Hamilton, O.

PLANERS, PORTABLE

Morton Mfg. Co., Muskegon Heights, Mich.
Underwood Corp., H. B., Philadelphia.

PLANERS, ROTARY

Newton Machine Tool Works, Inc., Philadelphia.
Niles-Bement-Pond Co., 111 Broadway, New York.
Pedrick Tool & Machine Co., 3639 North Lawrence St., Philadelphia.
Underwood Corp., H. B., Philadelphia.

PLATE ROLLS

Niles-Bement-Pond Co., 111 Broadway, New York.
Ryerson & Son, Joseph T., 2558 W. 16th St., Chicago.

PLATES, STEEL

Moltrup Steel Products Co., Beaver Falls, Pa.
Ryerson & Son, Joseph T., 2558 W. 16th St., Chicago.

PLATES, SURFACE

Brown & Sharpe Mfg. Co., Providence, R. I.

PNEUMATIC DIE CUSHIONS FOR POWER PRESSES

Marquette Tool & Mfg. Co., 331 West Ohio St., Chicago.

PNEUMATIC TOOLS

Hannifin Mfg. Co., Kolmar Ave. and Lexington St., Chicago.
Ingersoll-Rand Company, 11 Broadway, New York.

POLISHING MACHINES

Abbott Ball Co., Elmwood, Hartford, Conn.
Besly & Co., Charles H., 120-B No. Clinton St., Chicago.
Bridgeport Safety Emery Wheel Co., Inc., Bridgeport, Conn.
Brown & Sharpe Mfg. Co., Providence, R. I.
Builders Iron Foundry, Providence, R. I.
Diamond Mch. Co., Providence, R. I.
Forbes & Myers, 178 Union St., Worcester, Mass.
Gardner Mch. Co., Beloit, Wis.
Myers Mch. Tool Corp., Columbia, Pa.
Production Machine Co., Greenfield, Mass.

An Illustration of How ARGUTO Oilless Bearings Lower Your Manufacturing Costs

Smoother than Grease

Outwears the best bronze metal

In sending in one of several repeat orders, a user writes:—

> "Before using ARGUTO, we had to re-babbitt these sleeves every few weeks.
> "The original installation of ARGUTO Bushings was made nearly five years ago and today they seem to be as good as when first put in. They certainly have relieved us of a lot of bother, trouble and expense."

On an average the metal bushings had to be re-babbitted every six weeks at an approximate cost of about $2.40 per bearing—more than the cost of an ARGUTO. There were six ARGUTOS in the first installation and the old type bearings would have been re-babbitted 30 times in the same period.

Figure the savings for yourself:—

30 x 2.40 = $72.00 saved per bearing
6 bearings = $432.00 total saved by six ARGUTOS

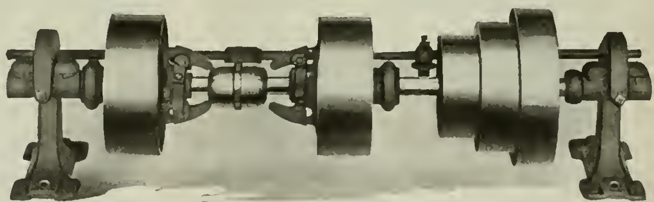
How many bearings in your plant? Figure up the savings you could make and then write for a trial order to the

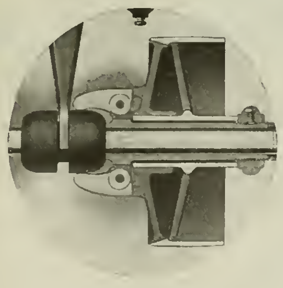
Arguto Oilless Bearing Company
Pioneer Manufacturers of Oilless Bearings
145 W. Berkley St. Wayne Junction, Philadelphia

ARGUTO OILLESS BEARINGS

Twenty Years of Successful Performances Back of

B & O Friction Countershafts





Seven Sizes—7" to 18" diameter
Two or Three Speeds
Sold Complete or in Parts

Between high speeds and constant starting and stopping, turret lathes exact a full measure of service from their countershafts. B. & O. countershafts are designed for this special purpose and make good on every count—efficiency, economy and durability.

We invite comparison—point by point—with similar equipment of any make; and are satisfied to leave the decision in your hands.

Send for the circular and location of nearest factory where you can see them on the job; or, better still, try one and make the comparison in your own plant.

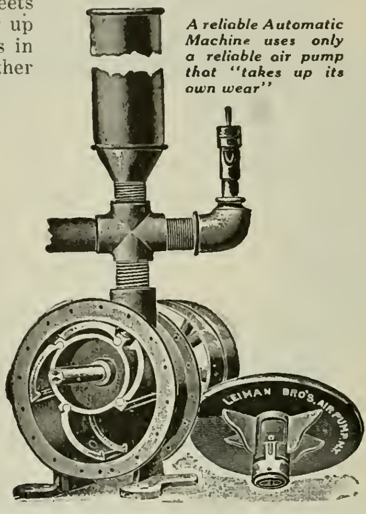
An Air Supply Without Storage Tanks

Either Vacuum or Pressure from the Same Machine

for operating any make of Gas or Oil burning furnaces—domestic oil burning heating plants—hand blow pipes for brazing, annealing or soldering—for sand blasting on metals, glass, hard rubber, fiber, wood and all articles of whatever size or shape—for wrapping packages—labelling bottles—banding cigars—milking cows—feeding sheets of paper in printing presses or ruling machines—picking up and conveying single sheets or entire books or magazines in gathering or other bindery machines—filling bottles and other receptacles with liquids.



A reliable Automatic Machine uses only a reliable air pump that "takes up its own wear"

LEIMAN BROS.

Rotary Positive—High Pressure

Blowers and Vacuum Pumps

Do all these things and more—you didn't think machines of this kind could do these things—tell us your ideas and you will be equally surprised, perhaps, at our answer.

G & P UNIVERSAL JOINTS

Smother Vibration

We aim to put quality into G & P Joints. Customers tell us we have succeeded. We carry seven stock sizes which take care of practically any work a universal joint is called upon to do. The wearing surfaces of G & P Universal Joints are scientifically case-hardened, making them long lived. There are no sharp corners, no screws or small parts to renew, and no corners to collect dirt. Write for details.

SYRACUSE SNAP GAGES

At Lower than Pre-war Prices

With the adoption of our new list, the sale price of the Syracuse Gage, for the time being at least, is below the 1914 level—lower in fact than ever before despite the fact that this instrument has been entirely redesigned and improved and is today the unquestioned leader in the Snap Gage market.

If you have a production job in your plant where accuracy is essential, equip that job and inspectors with the Syracuse Gage. The result will be its adoption for all future requirements.

"the Gage with the Square Pins"

STYLE "A"

Standard Square Pin Gage, 24 sizes up to 12" capacity in stock for immediate shipment. Larger sizes to order. Details and New Low Prices in Catalog 4.

Meldrum - Gabrielson Corporation
Syracuse, N. Y., U. S. A.

Die Making Machine

"A Toolmaker in Itself"

OLIVER OF ADRIAN

Made in seven different types

Dies, gauges, templets and the like can be sawed, filed, and lapped on this machine. It accomplishes the work, on the average, in from 30 to 60 per cent of the time ordinarily required for handwork. It is useful for experimental work as well as for regular production.

Ask for the "Oliver" Bulletin

OLIVER INSTRUMENT COMPANY
Adrian **Michigan**

Wel-don Tools are "Double-End"

Especially adapted to rapid milling of slots in steel and iron from the solid. Heretofore it was necessary to drill a number of holes and to make several cuts in milling the slot. High surface speed insures the best results. Send for catalogue.

WELDON TOOLS

THE WELDON TOOL COMPANY
321 Frankfort Ave. **Cleveland, O.**

ETTCO

Self-Gripping MANDRELS

Accurate

When you have bushings to turn down or grind in a hurry, when alignment with the bore must be accurate within half a thousandth limits, you'll appreciate the unique advantages of Ettco Self-Gripping Mandrels.

They're as accurate as solid arbors and as fast as hand or air operated expanding mandrels.

The heavier the chip, the tighter they grip! Let us explain—or better still, send you one for 30 days to try at our expense.

EASTERN TUBE & TOOL CO., Inc.
594 JOHNSON AVENUE
BROOKLYN, N. Y.

There's A Mighty Good Reason

THERE'S a mighty good reason for "Cleveland" drills coming out on top in test after test and better still, in year in and year out service.

Of course these drills are mechanically right or the results would not be so uniformly successful.

But of greater importance is the fact that there is a type of "Cleveland" drill to fit the conditions in your shop. In the "Cleveland" line you can find the drill which will give you the smallest initial cost and least cost per hole for we present the only complete line of drills including Carbon, MEZZO and High Speed.

If you have a job that is causing trouble or on which drilling costs are too high, tell us about it. We will give it expert attention without cost or obligation to you. Won't you let us hear from you?
